3RD SECTION — WORKING

OPENING MEETING

4 July 1910, 4.50 p. m.

PROVISIONAL PRESIDENT, MR. FAIRFAX HARRISON,
MEMBER OF THE PERMANENT COMMISSION OF THE CONGRESS.

The President. (In French.) — Gentlemen, the Permanent Commission has charged me with the installation of the 3rd section. It has requested me to propose to you that the following shall be the officers forming the bureau of this section :

1° As president : Mr. DIETLER, engineer, formerly president of the board of the St. Gothard Railway, member of the Permanent Commission of the Congress. (*Applause.*)

2° As vice-presidents : Mr. TONDELIER, traffic director of the Belgian State Railway, member of the Permanent Commission of the Congress; Dr. R. ULBRICHT, member of the Board of Works, councillor of the royal ministry of finance of Saxony, member of the Permanent Commission of the Congress; and Mr. WEISS, chief engineer of bridges and roads, manager of the French Eastern Railway, member of the Permanent Commission of the Congress. (*Applause.*)

3° As principal secretaries : Mr. AHONEN, general manager of the Finland State Railway; Mr. KAREISCHA, State councillor, professor, engineer of ways of communication, vice-manager of the traffic department of the ministry of ways of communication of Russia; and Mr. VERLANT, assistant chief engineer of the Paris-Lyons-Mediterranean Railway. (*Applause.*)

(Mr. Fairfax Harrison vacated the chair which was then occupied by Mr. Dietler.)

Mr. Dietler. (In French.) — Gentlemen and dear colleagues, as it is now not the time for official speeches, I limit myself to thanking you for the confidence you have just shown in me and for the honour you have bestowed on my country in appointing me president of the 3rd section.

As you know, there is quite enough

63385

before the Congress, and the technical world expects from us solutions which are such as to help the development of the railway industry. Hence, we must work. As far as I am concerned, I shall do all that is possible to render our labours fruitful and I am convinced that you on your side will do the same. (*Approval.*)

— On the proposal of the president, the SECTION then appointed the other members of the bureau and drew up provisional agenda.

SECTION III : WORKING

[656 .211 & 656 .212] QUESTION IX

LARGE STATIONS

A. Large passenger stations. — *Best arrangement of tracks so as to increase their working capacity and ensure safety in shunting operations. Improved mechanical appliances for the conveyance of luggage, etc.*

B. Large goods stations. — 1° *Arrangements of tracks :* a) *to allow the continuity of movement of vehicles which require shunting and which are separate from the time the train bringing them has arrived until the train taking them away is being made up;* b) *to prevent such movement from being interfered with by the arrival or departure of trains;* c) *to stop without shock such separate vehicles at the end of the successive movements required;* d) *to start them off again.*

2° *New appliances for handling goods.*

Reporters :

America. — Mr. H. A. Jaggard, superintendent, Pennsylvania Railroad.

Russia, Austria, Hungary, Rumania, Bulgaria, Servia and Turkey. — Mr. A. Kain, engineer, inspector of the Hungarian State Railway.

Other countries. — Mr. Jullien, chief way and works engineer of the Orleans Railway, and Mr. Leverve, assistant traffic manager of the Orleans Railway.

QUESTION IX

REPORT N° 1

(All countries except America, Russia, Austria-Hungary, Rumania, Bulgaria, Servia and Turkey)

By Mr. JULLIEN,

CHIEF WAY AND WORKS ENGINEER OF THE ORLEANS RAILWAY,

and Mr. LEVERVE,

ASSISTANT TRAFFIC MANAGER OF THE ORLEANS RAILWAY.

In the present report, we shall reproduce in succession the different questions contained in the list of questions which we sent out to the administrations concerned; at the end of each we shall give a summary of the answers we have received, and the general impression to be drawn from them. We shall then at the end give the conclusions to which we consider they lead.

LITTERA *A*.

Large passenger stations.

1° *Have you adopted any special arrangements in order to increase the working capacity of your stations and to ensure the safety of the shunting operations? More especially :*

a) Are the tracks for main line trains grouped together in a set separate from the set of tracks used for suburban trains?

The arrangements generally adopted in order to increase the working capacity of

large passenger stations consist in the separation and specialization of the installations used for the different station services.

In the first place, everything in connexion with the operation of goods trains is kept separate; special tracks not affecting the passenger tracks are used for the purpose, and even the local services and the shunting operations are dealt with at one or several separate stations.

Special premises are used for the parcels, perishables, vegetables and cattle traffic, and also for the mails; and when there is enough, such traffic trains are run for parcels or for mails only. (There is one fast train, between Paris and Marseilles, carrying mails only.)

Finally, the different lines run in to the station each on a separate track, and these tracks are grouped according to the importance of their traffic, care being taken to avoid crossings, at the same level, in the case of the regular service.

The safety of the arrival and departure movements is ensured by mechanical or electrical interlocking gear. The number of switches on main lines is limited to as few as the exigencies of the service allow. When the subordinate lines have to be connected with the main lines, they are equipped with scotch blocks or, as seems preferable, with refuge sidings.

At the large stations where there is both a large suburban traffic and a large main-line traffic, it is advisable to keep separate the installations for the suburban traffic and the main-line traffic, as the services have different requirements. On lines with very much traffic, the tendency has been to double the tracks by placing alongside the main lines double tracks to accommodate the suburban traffic.

The distinction between suburban tracks and main-line tracks however only exists, in an absolute manner, at some large stations where the suburban traffic is of exceptional importance. We may mention more especially the stations of the Western-State system at Paris : Montparnasse, Les Invalides and St. Lazare.

The Paris St. Lazare station is at present in a state of alteration. The work at present carried out there is intended to increase the capacity of the station and of the lines which go there. The present number of tracks is twenty-seven, sixteen of which are used for the suburban service. This will be increased to thirty-three, including eighteen suburban tracks; six of these will be electrified and placed on a lower floor. The station will thus have tracks on two floors, the system adopted being thus analogous to that which is being carried out at New York, in the case of the terminal station of the New York Central and Hudson River Railroad.

At a large number of stations where the suburban installation and the main-line installation are not kept strictly separate, some tracks are however exclusively reserved for the suburban service.

At the Paris Nord station, there are fifteen tracks used for the suburban service only, and either tramway trains or ordinary trains are run on them. But a certain number of other tracks are used either for main-line, of for suburban trains; it

was possible to group the trains of these two services at certain hours of the day. Such an organization makes a more complete utilization of the station tracks possible.

It sometimes happens at roadside stations that secondary lines are run from dead-ended platforms placed at the ends of the passenger-station building (for instance, North Eastern Railway station at York, Strasburg station, Hirschberg station in Silesia). We may also instance the arrangement of the stations at Berlin, where the metropolitan Stadtbahn lines are together with the main lines; the same is the case at the Hamburg stations, with the electrically-operated lines of the Stadtbahn.

In addition to the separation and the specialization of the installations, the working capacity of the stations is also increased by reducing to a minimum the shunting operations required, such as changing the composition of the trains, and by making these independent of the arrival and departure movements of the trains.

Such measures are more especially necessary in the case of suburban services on account of the density of the traffic.

---

b) Are the suburban tracks arranged so as to reduce shunting operations to a minimum? Have you for instance adopted, as the solution, end loops at certain stations, as at Boston station (U. S. A.)?

The way in which the tracks are arranged so as to make it possible for the locomotives to pass from the head to the tail of trains, such as running lines connected by switches to passenger tracks at both ends, is the same in the case of the main lines as in that of suburban lines.

As a rule, any alteration in the composition of suburban trains is avoided, particularly if the traffic is dense and regular. The only provision then made at the terminus stations consists in arranging the tracks in such a way that locomotives can easily be changed or taken quickly from one end of the train to the other.

At the Paris Bastille station, an electric traverser connects the dead-ends of the tracks at the station, and is used to shift the locomotives from one track to another.

At the Paris Quai d'Orsay terminus station, where the lines are electrified, an electric traverser makes it possible to shift the motor cars from one track to another. But it is, as a principle, not utilized for the suburban service. The electric service on the line from Quai d'Orsay to Juvisy is as a matter of fact effected by sets of carriages always arranged in the same way; they are propelled by two motor cars, placed at the head and at the tail, which are controlled simultaneously by a driver who is at the head of the train. All the driver has to do at the terminus is to move from one end of the train to the other. This is a very valuable advantage of electric traction.

*

Fig. 1. — **Shunting y**

The object of the depot at Grunewald is to receive during the night part of the trains, and locomotives, which run on the metropol extension of the metropolitan (immediately to the west of the Grunewald passenger station), with wich it is joined by a special double-tra

In order to avoid any level crossings of the main lines, the depot is placed between the three main lines. It is to include fived se four only, the sets A, B, C, D, are actually built; they can accommodate 40 trains.

Nearly all the tracks of these five groups are connected by switches at both ends. The tracks of group A have an available lengt washing the trains, and also, at hours of little traffic, for storing the trains.

It is a principle, that the composition of trains is not modified; thus sorting sidings are unnecessary. When damaged carriages ha the sidings well connected with the arrival and departure tracks as well as with the locomotive sheds, for the trains must be able to enter

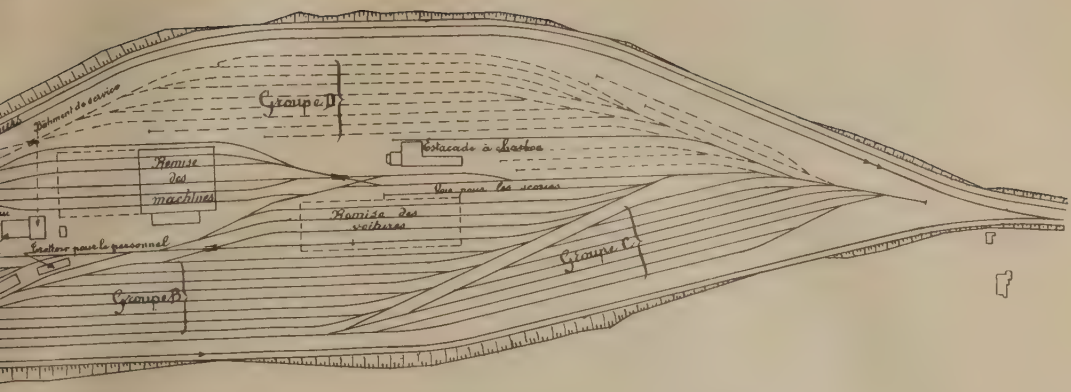
All the accessory installations had also to be provided, such as locomotive sheds, staff offices, washing appliances, etc.

Explanation of French terms : Trottoir = Platform. — Groupe = Set. — Gare de marchandises = Goods station. — Délivrance des billet — Voies pour les scories = Track for ashes. — Estacade à charbon = Coal tips. — Château d'eau = Water-crane. — Voie de voyage = Heating apparatus. — Magasin = Store. — Bâtiment de service = Office building. — Trottoir pour le personnel = Platform for en

At the terminus stations of the lines operated with tank locomotives with a small wheelbase, there are also used turn-tables placed at the ends of the main lines and the running lines which are arranged in such a way that the turn-table in question can be used for two or three of them.

These turn-tables make it possible, by one single operation, to direct the locomotive so that it can pass from one track to another.

The solution of the end loop, which was first recommended by the French Northern Railway and which has been applied so largely on the Paris metropolitan system, does not appear to be used in Europe for main-line stations. The only instance we know of elsewhere is at Boston-South, U. S. A., and we believe that even that is at present not being used.



newald near Berlin.

lines, as well as on the eastern suburban lines. During this time the trains are examined and cleaned. This depot is on the western at the movements of the train are quite independent of the passenger trains running on the main line.
ch will accommodate 52 metropolitan or suburban trains about 180 metres (590 feet) long, as well as the spares necessary. Of these five sets,

219 yards) and can take one train; nearly all the tracks of the other groups can take two trains. Group A is utilised during the day for

or when other similar operations of minor importance are carried out, the depot tracks are used. It has been necessary to have short period of time. When the service starts, all the trains have to leave the depot within an hour and a half or two hours.

very. — Voies de grands parcours = Main lines. — Remise des machines = Locomotive shed. — Remise des voitures = Car shed. arcours = Passenger main-line. — Voie de jonction avec la gare de remisage = Junction with station depot. — Chaufferetterie ment de halte = Remises for stopping.

c) How are tracks arranged so as to make it possible :

I) *to change locomotives quickly ;*
II) *to add or take off carriages ;*
III) *to make up trains, or to bring to the platform trains made up on a special set of sidings ?*

I. — The tracks to enable locomotives to be changed quickly are, as a rule, tracks placed at the side of the main line on which this change is to be effected.

These tracks are connected at both ends by means of switches, or else are dead-ended and then connected in the departure direction of the trains which have to have their locomotives changed. Mereover, the locomotive sheds are connected with the tracks at the station by one or two independent lines.

At large stations, particularly if the locomotive sheds are at some distance from the centre of the station, it is very useful to have near the platforms and between the main lines, sidings for the locomotives and even to equip these sidings with a turn-

table, a water-crane and a coal store, so as to form a sort of auxiliary locomotive depot, readily accessible.

This arrangement appears advisable at large stations when the connections do not make it possible to run from the chief locomotive sheds to the different platform tracks without blocking a number of lines.

II and III. — The arrangement of tracks to make it possible to add or take off carriages is the same as that adopted in the case of locomotives and described above.

But it is also necessary to have sets of sidings available sufficiently large, for making up and washing the trains, connected with the platform tracks by lines as independent of the main lines as possible.

At the Dresden Altstadt station, a special set of sidings is provided for making up trains; the ready trains are then taken from there to the platforms of the station, which are at a distance of 1·5 kilometres (0·93 mile).

When the number of trains which have to be stabled is very large, actual depots are built for the purpose, such as the Grunewald depot near Berlin (see plan fig. 1) for stabling the metropolitan and suburban trains, where there is accommodation for 52 trains each 180 metres (590 feet) long. We reproduce in the appendix a note on the subject of this station, which was sent to us by the Berlin Direction of the Prussian-Hessian State Railway, together with a plan of the depot.

---

d) Have you any stations with separate floors, in which the tracks are, either all or in part, either on an upper floor or in a basement, the ground floor being used for different offices (enquiry offices, booking offices, luggage offices)?

In the case of a mixed arrangement, that is to say, when some of the tracks only are at another level than the ground floor, which tracks are at that level and which tracks are on the ground floor?

In the case of stations with separate floors, how are the different services distributed between the ground floor and the other floor?

What circumstances : topographic location, difficulty of widening, etc., have led to the adoption of separate floors?

What advantages do you consider this arrangement to have to make up for the increased amount which as a rule such a station costs to build and run?

The solution of a station with several floors, presents several very serious advantages : in the first place, at a station where there is much traffic, and where consequently the passengers must not be allowed to walk across the lines, they save the passenger a useless ascent or a useless descent.

It makes it easy to carry out the luggage service without inconveniencing the passengers. It does not in any way interfere with the urban traffic, as the streets of the town pass below or above the iron roads. It thus contributes to the safety of the traffic both on the railway and on the streets of the town.

Finally, it reduces as a rule the area of land required, and consequently the expenditure is less.

From the latter points of view, this solution may become the only possible one when building a new station or enlarging an old one which is in the middle of a large town. Such is the case at the Quai d'Orsay, Invalides and St. Lazare stations at Paris.

The solution of a station with several floors is very usual in Germany, and it may be said that it is always adopted when circumstances make this possible.

This solution has also been adopted, but less frequently, in France, particularly at the Quai d'Orsay and the Invalides stations. It is proposed, as we have already stated, to apply it at the St. Lazare station : the suburban lines will then be placed under the main lines, that is to say, at the same level as the neighbouring street.

The St. Lazare station will then be of the mixed type, like the Dresden Altstadt station, where the lines are also at different levels : those which run through the station are at the higher level and those for which it forms the terminus are at the lower level.

In the case of stations with floors, the floor which is on the same level as the public streets is as a rule used for the booking offices and for luggage offices, both for the receipt and the distribution of luggage. The other service offices and the refreshment rooms are on the other hand on the same level as the platforms.

The waiting rooms are sometimes on the ground floor, sometimes at the same level as the platforms.

---

e) Have you adopted the solution of « double platforms » applied more especially on the French Northern Railway at St. Omer and Valenciennes stations (Revue générale des chemins de fer. November 1904 and May 1907) ?

This solution does not seem to have been adopted, apart from the French Northern Railway (Valenciennes and St. Omer stations), except at the Mans station (Western-State). Below we give diagrams showing the arrangements at these three different stations (figs. 2 to 4).

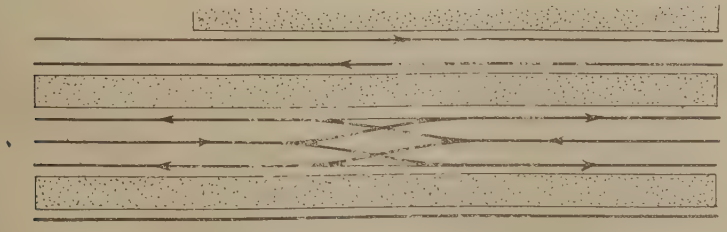


Fig. 2. — St. Omer station.

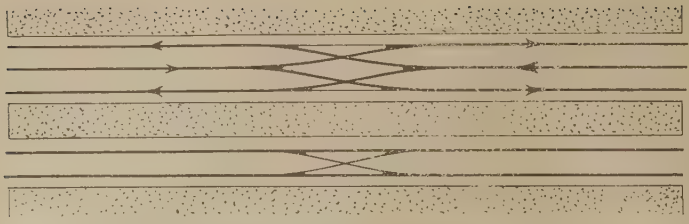

Fig. 3. — Valenciennes station.

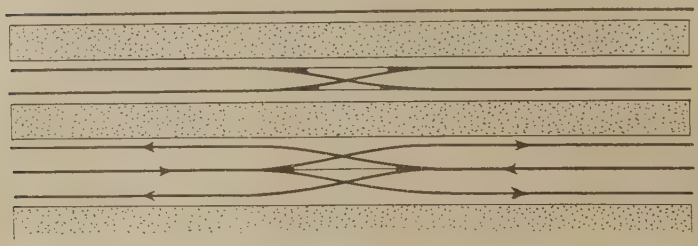

Fig. 4. — Mans station.

The administration of the Alsace-Lorraine State Railway propose to adopt a similar arrangement, as show in the diagram below (fig. 5).

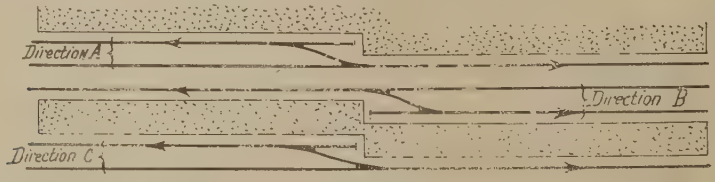

Fig. 5.

---

f) Please enclose in your answer plans of the passenger station or stations on your railway, of each of the types considered (station at one level, mixed station, station with separate floors), which seem to you to satisfy most completely the two desiderata mentioned above : namely to increase the working capacity and the safety of the shunting operations. It would be of interest to state how many reception tracks for passenger trains there are at the stations in question, and how many trains are received on the whole of these tracks during twenty-four hours.

We are unable to reproduce the numerous plans we have received, and in which the arrangements described above are more or less carried out. We will only give

some of the figures supplied to us, showing the maximum number of trains per day at some of the stations, as well as the number of tracks available at those stations.

GERMANY.

Hamburg, 10 tracks : 217 main-line trains; 264 metropolitan trains.
Breslau, 9 tracks : 225 trains.
Frankfort, 18 tracks : 625 trains.
Dresden-Altstadt, 13 tracks : 227 trains.
Strasburg, 7 tracks : 274 trains.

GREAT BRITAIN.

London (Liverpool street), 18 tracks : 600 trains; 95,000 passengers.
Nottingham (Victoria), 14 tracks : 420 trains.
Glasgow (Caledonian), 13 tracks : 300 trains.

FRANCE.

Paris-St. Lazare, 27 tracks : 600 trains; 83,000 passengers.
Paris-Nord, 28 tracks : 500 trains.

SWITZERLAND.

Bale, 10 tracks : 219 trains.
Zurich, 11 tracks : 307 trains.

2° Please describe the mechanical appliances you have, either at the stations with separate floors, or at the stations at one level :

a) For the conveyance of luggage (lifts, motor tricycles, travelling endless belts, etc.).
b) For the conveyance of passengers (lifts, travelling inclines, moving staircases, etc.).
c) To your answer please add particulars add drawings of the appliances mentioned under a) and b).

---

a) Lifts for the luggage service are used very extensively in Germany. This naturally results from having stations with several floors. These lifts are either hydraulic or electric.

The electric lifts are generally actuated by an endless screw acted on by the electric motor; this screw takes into the screw thread of the piston. The endless screw runs in an oil bath.

At Hamburg, an endless belt driven electrically is used; the arrangement is shown in the following figures (fig. 6).

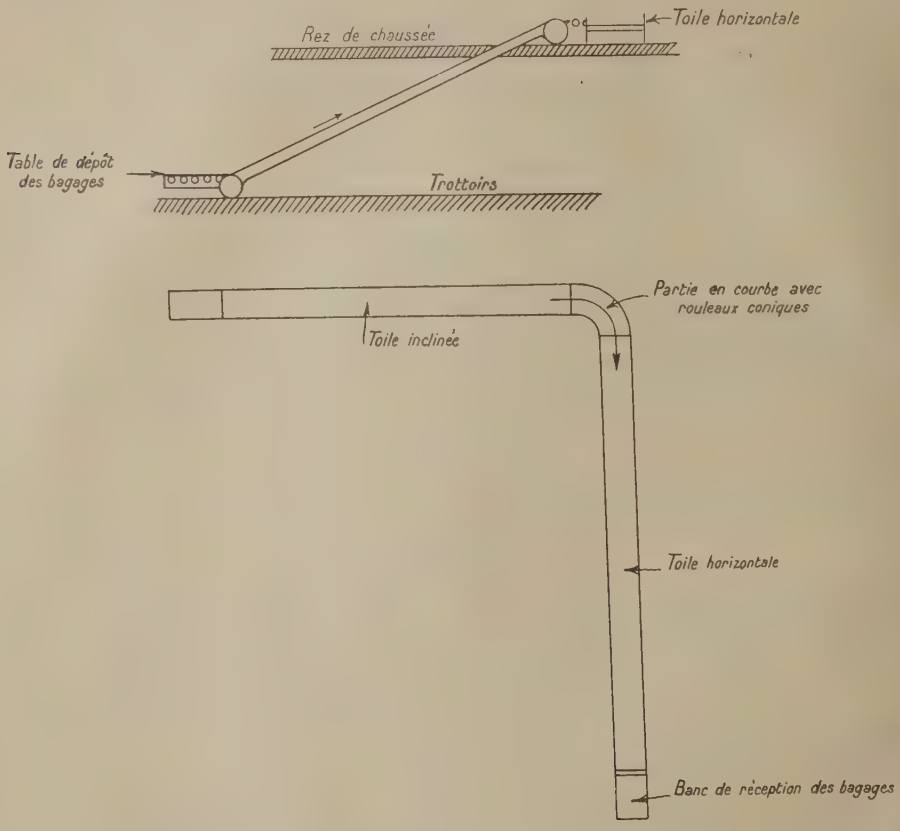

Fig 6.

Explanation of French terms : Rez-de-chaussée = Ground floor. — Toile horizontale = Horizontal belt. — Table de dépôt des bagages = Table for the luggage — Trottoirs = Platform. — Toile inclinée = Inclined belt. — Partie en courbe avec rouleaux coniques = Curved part wish coned rollers. — Banc de réception des bagages. — Table for receiving the luggage

At the Quai d'Orsay station, at Paris, there are also electric lifts; endless belts are extensively used for the conveyance of luggage.

A detailed description of this installation is given in the July 1901 number of the *Revue générale des chemins de fer;* it consists principally of an inclined belt to overcome the difference of height of 5·17 metres (17 feet) which exists between the tracks and the upper floor where the luggage is delivered; then of a canted portion where

the luggage is tilted on to benches the top of which is also movable. The luggage is thus brought along in front of the porters who take it as it passes. The plan and section (see fig. 7) show the arrangement of the installation.

The Paris Invalides station also has such belts for the conveyance of luggage.

The automotor tricycles tried in the United States by the Pennsylvania Railroad, have also been tried by the French Northern Railway.

b) Passenger lifts are but little used at the main-line stations; they seem chiefly used at city stations, as in London, where the difference of level is considerable; they are then constructed in such a way as to be able to accommodate a large number of passengers at once.

At Hamburg station, however, there are lifts for this purpose; also at some of the Paris stations, for instance at Montparnasse and Quai d'Orsay; they are however but little used by the public.

On the other hand, there is installed at Quay d'Orsay station a moving staircase which is much appreciated by the public. Such a staircase is also used at the Magasins du Bon Marché and at the Père-Lachaise station (Paris Metropolitan); and it has more than doubled the rate of movement of the passengers. A description of it is given in the June 1908 number of the *Revue générale des chemins de fer*. We give views and photographs of it in figures 7 to 11.

LITTERA *B*.

Large goods yards.

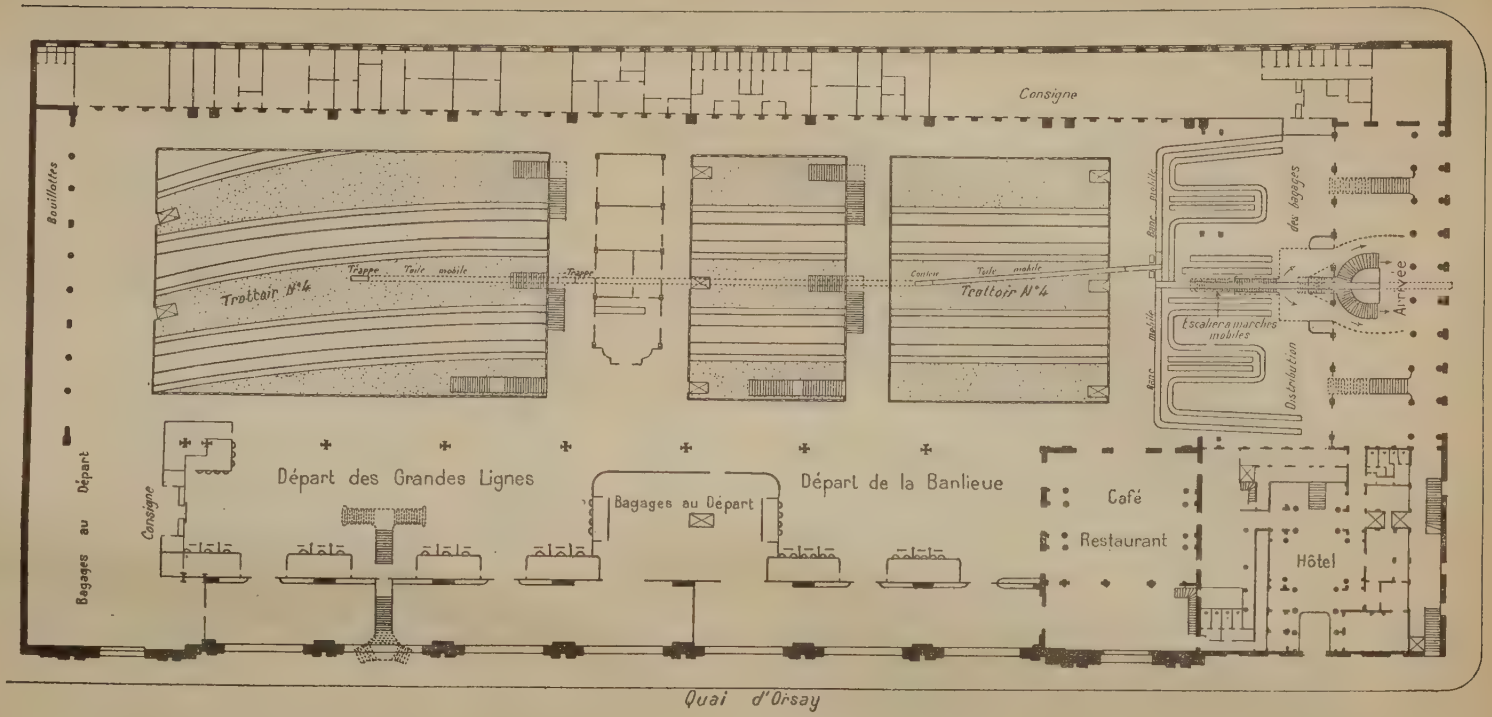
1° *Are the sidings at some of your sorting and shunting yards arranged so as to ensure the continuity of the movement, in one given direction and consequently without any reversal, of the cars to be dealt with, from the time an arriving train is received until a train is made up and ready to leave?*

Generally speaking, the large sorting and shunting yards of recent construction consist essentially of four sets of sidings over which the wagons which are being sorted pass from their entry to their egress:

The reception sidings on which the trains to be sorted are received when they arrive, and from which the wagons are sent on direct either by being shunted on to a saddle-back, or by the effect of a continuous incline on to the set of sorting sidings;

The set of sorting sidings which includes a number of sidings varying with the number and the importance of the lines terminating at the station and of the sorting which has to be effected;

Plan du rez-de-chaussée.



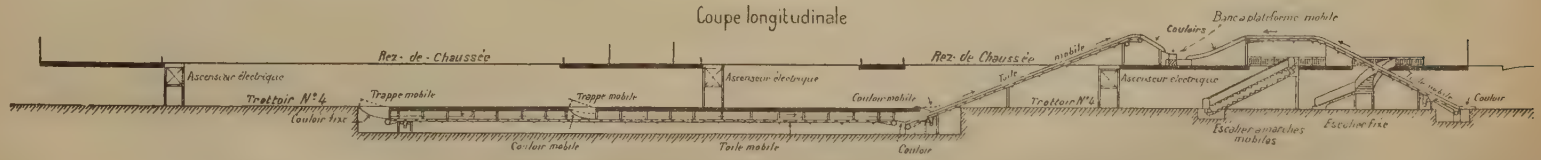


Fig. 7. — Installation of a staircase with moving steps at Quai d'Orsay station.

Explanation of French terms : Plan du rez-de-chaussée = Plan of ground floor. — Bagages au départ = Departure, luggage. — Consigne = Cloak room. — Départ des grandes lignes = Departures, main line. — Départ de la banlieue = Departures, suburbs. — Escaliers à marches mobiles = Staircase with moving steps. — Distribution des bagages = Distribution of luggage. — Arrivée = Arrival. — Toile mobile = Travelling belt. — Trappe = Trap. — Trottoir n° 4 = Platform No. 4. — Banc à plateforme mobile = Bench with movable top. — Bouillottes = Heating apparatus. — Escalier fixe = Fixed staircase. — Ascenseur électrique = Electric lift. — Rez-de-chaussée = Ground floor. — Coupe longitudinale. = Longitudinal section. — Trappe mobile = Movable trap. — Couloir = Passage. — Couloir fixe = Fixed passage. — Couloir mobile = Movable passage.

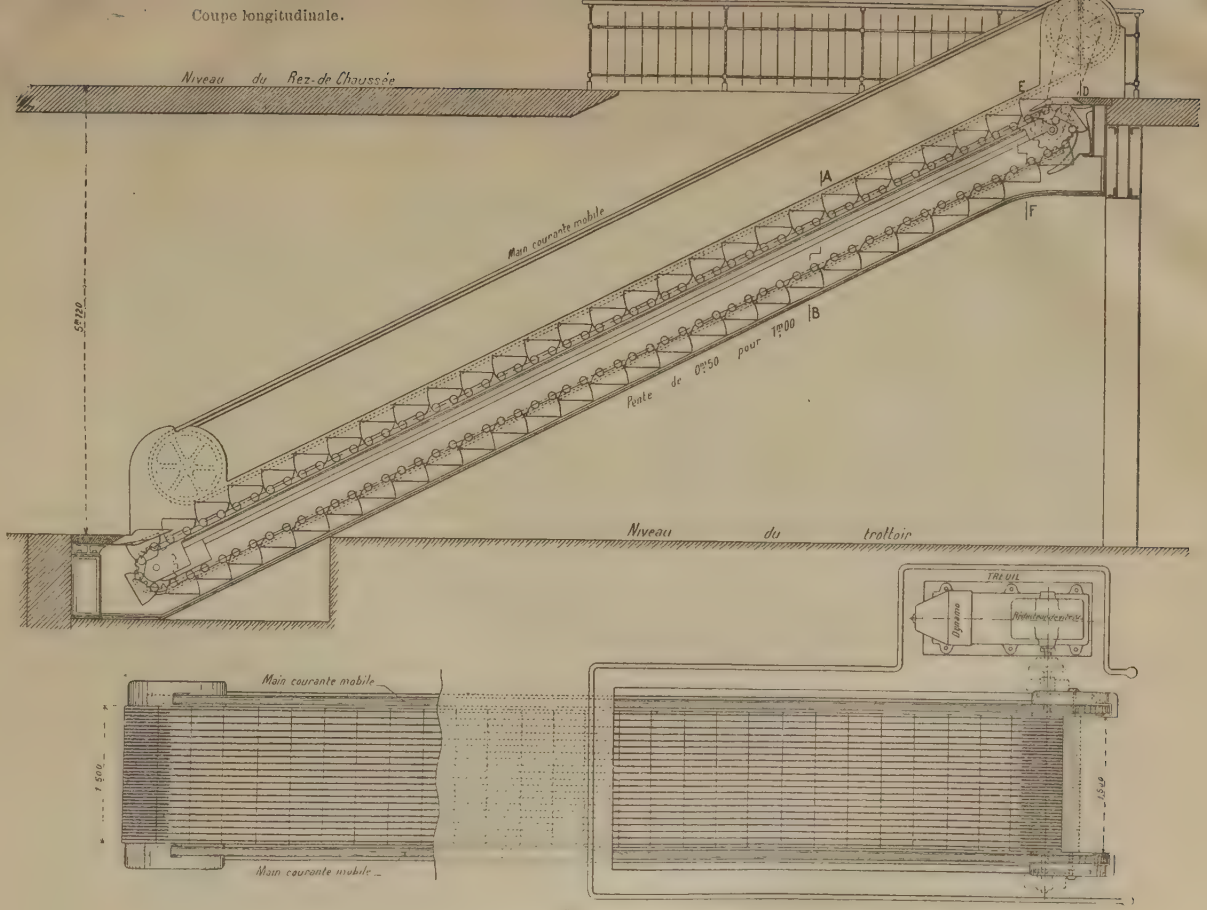

Fig. 8. — Installation of a staircase with moving steps at Quai d'Orsay station.

Explanation of French terms : Niveau du trottoir = Level of platform. — Niveau du rez-de-chaussée = Level of ground floor. — Coupe longitudinale = Longitudinal section. — Main courante mobile = Moving hand rail. — Treuil = Windlass. — Réducteur de vitesse = Speed reducer. — Pente de 0.50 mètre pour 1 mètre = Slope of 1 : 2.

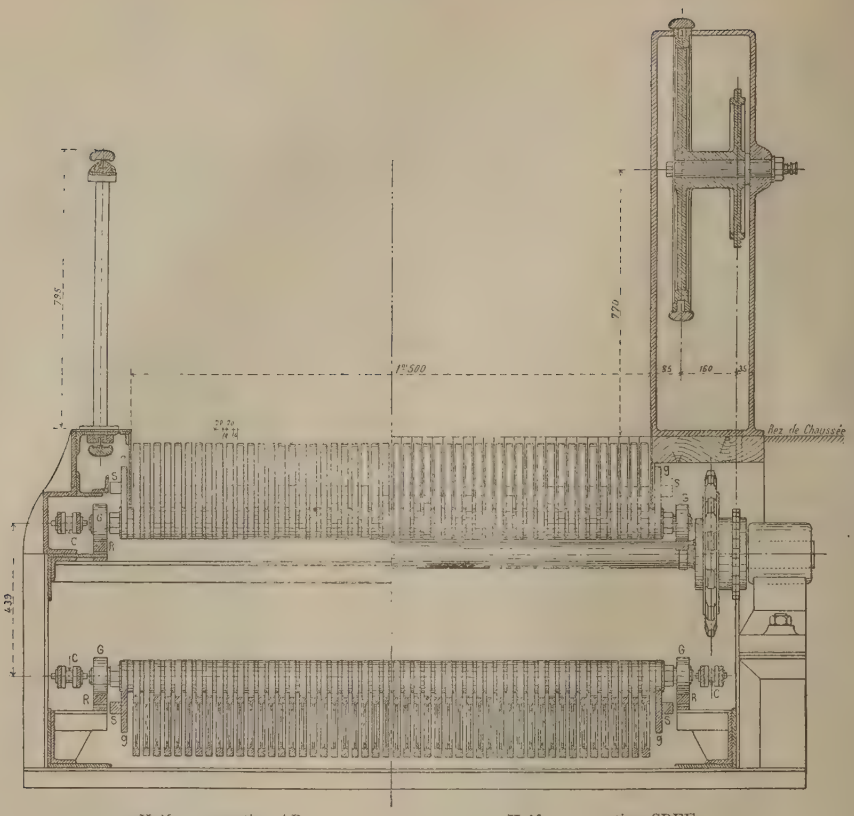

Fig. 9. — Installation of a staircase with moving steps at Quai d'Orsay station.

Explanation of French term : Rez-de-chaussée = Ground floor.

From these sorting sidings the wagons pass, either by continuous incline, or after being shunted on to a saddle-back, on to one or more smaller sets of sidings or gridirons, where the geographical classification is effected;

From these gridirons the wagons are taken either by the action of gravity or by means of a shunting locomotive, on to the departure sidings.

The system described under 1° of the list of questions has now been in existence for a long time at Terrenoire (near St. Etienne, Paris-Lyons-Mediterranean Railway) and at Edge Hill (near Liverpool, London and North Western Railway). It is being applied more or less completely at those places where local conditions admit of it. This has been done at Lumes (near Charleville, French Eastern Railway) and is at

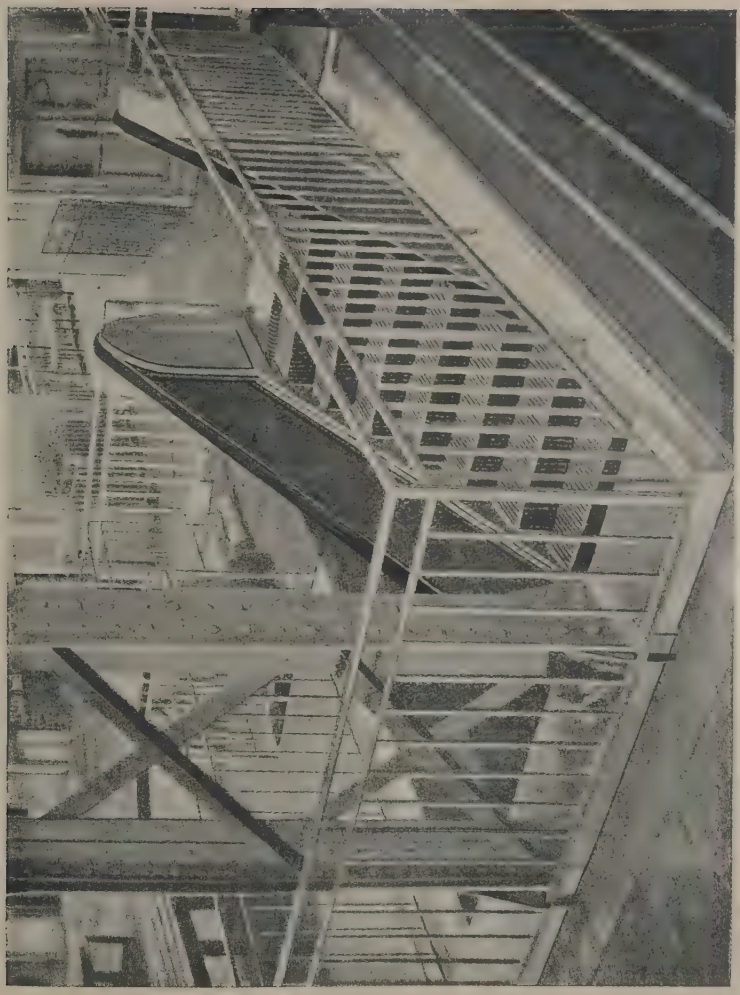

Fig. 10. — Installation of a staircase with moving steps at Quai d'Orsay station.

Fig. 11. — Installation of a staircaise with moving steps at Quai d'Orsay station.

present being done at those sorting yards which are being rearranged or constructed on the Orleans Railway (Les Aubrais, St. Pierre-des-Corps, Vierzon, Coutras, etc.).

The same is the case at the more recent large sorting yards in Germany : Mannheim, Nuremberg, Dresden, Osterfeld-Süd (near Essen), Hausbergen (near Strasburg), Engelsdorf (near Leipzig), Brockau (near Breslau), etc.

The same is the case at the large sorting yards in Great Britain : Dunford and Wath (Great Central), Shildon (North Eastern), Ross (Caledonian), Temple Mills (Great Eastern), etc.

The Belgian State Railway has as yet no yards of this kind, but is working at projects of this kind for the important yards Schaerbeek and Welkenraedt.

In Switzerland, the Zurich and Bâle sorting yards are partly of this kind.

---

a) Are these sidings on a continuous incline so that the cars can be sorted by gravity without requiring a locomotive, or do they consist of successive sets of sidings on the flat, commanded by saddle-backs on to which the trains are pushed by the locomotive? Are there successive gridirons which allow a train to be classified according to destination and on which the making up of a train can be completed ?

As a rule there are saddle-backs; the lines are then on the flat or on a gentle gradient in order to facilitate the movement of the wagons.

Good results are generally obtained by having as profile of the lines first a descending gradient of 20 to 30 or 35 per mil from the top of the saddle-back, and then about 40 metres (44 yards) of a 15 per mil gradient to the switches of the sorting sidings, the latter being about 200 to 300 metres (219 to 328 yards) long and having a gradient of 4 to 5 per mil.

If the sorting sidings are on a long continuous incline, the sorting and marshalling of the wagons is much facilitated; this is the system very generally adopted in England, where Edge Hill goods yard is a typical instance of such an installation.

We can also mention the following cases in France and Germany, where the goods yards are on continuous inclines without saddle-backs :

FRANCE.

Terrenoire, on the Paris-Lyons-Mediterranean Railway. A long continuous incline of about 14 per mil, extending from one end of the yard to the other.

GERMANY.

Nuremberg, gradient of 5 to 16 per mil on the reception sidings, of 12·5 per mil at the switches of the sorting sidings, of 5 per mil on the sorting sidings.

Dresden-Friedrichstadt, gradient of 10 per mil.

*

The use of gridirons for the sorting sidings has a tendency to become general. Sometimes there is only one gridiron, sometimes there are two, one after the other.

Sometimes the wagons descend by gravity on a continuous incline, passing over the sorting sidings and marshalling sidings to the departure sidings, as at Dresden, Nuremberg and Strasburg; sometimes the wagons are hauled by a locomotive from the sorting sidings up to a saddle-back from which they run on to the marshalling sidings, as at Mannheim and at Lumes.

Whether a saddle-back or a continuous incline is used for the sorting sidings or for the marshalling sidings appears to be in reality determined by the local topographical conditions. The saddle-back system will accordingly be the more convenient in most cases.

When there is a continuous incline, one is led to carry out all the sorting operations in one and the same direction, for all the different lines terminating at the yard. The reception sidings for all the lines are grouped together at one end A, the departure sidings at the other end B, and all the wagons are sorted in the direction A to B.

The wagons on lines terminating at one end of the station thus as a rule make an unnecessary journey at their arrival and at their departure.

At saddle-back yards on the other hand it is possible, when the traffic is sufficiently important, as at Mannheim, to have two series of sidings laid side by side, each for the wagons arriving at the opposite ends of the station; these are then sorted in two opposite directions.

---

b) What system is adopted for stopping and again starting the cars in the two cases mentioned above (hand brakes, sprags, skids, etc.)?

Are all the cars which are shunted at yards with continuous inclines, fitted with hand brakes? How is the work carried out when this is not the case?

In England, practically all the wagons are fitted with brakes, and sprags and skids are only used very exceptionally. In other countries, the most usual method for stopping wagons is the use of skids.

A special form of skid or rail-brake (*Gleisbremse*) is rather extensively used in Germany. This skid is placed a little below the top of the saddle-back; its object is to reduce the speed of certain sets of wagons which otherwise might become accelerated too much. This skid has limited travel; that is to say, at a given point there is a special device which throws the skid off while the wagons continue their journey (1). A skid of this type is also used on the French Eastern, at the Lumes sorting yard. The use of such a rail-brake makes it possible to give the saddle-back

(1) See *Bulletin of the Railway Congress*, 1909, p. 3042.

the gradient necessary for the most unfavourable conditions of rolling, especially when there is a strong head wind. When there is a calm or when the wind comes from behind, the speed of the wagon or set of wagons is reduced by means of this rail-brake before the switches of the sorting siding are reached.

---

c) *What arrangements are adopted for stopping run-aways (chain drags, safety sidings, sand tracks, etc.)?*

The arrangements seem to be very little used and only applied in very exceptional cases.

The London and North Western Railway states that the chain drag which in in use at Edge Hill, near Liverpool, has given excellent results; it has already come into operation more than two hundred times without a failure.

2° *Have you adopted any arrangement of tracks making it possible to eliminate any interruption of the shunting, sorting and making up operations owing to the arrival and departure of trains?*

All the railway administrations agree in recognizing the great interest there is in realizing this condition. It results in a saving in working expenses in consequence of a better utilization of the shunting locomotives and of the staff, and there is also a saving in the time during which the wagons which are to be sorted have to stand still. Consequently, the reception sidings are less encumbered, and their number can accordingly be reduced.

But local conditions do not always make it possible to carry out this programme fully.

3° *What importance do you attach to the realization of the different preceding conditions (continuity and uniform direction of movement, elimination of all interruption to shunting operations)?*

Does the advantage obtained by this realization justify, to the same extent in each case, the large size to be given to the yards and the resulting expense?

It is generally thought that when a new yard is in question, which is to accommodate a very large amount of traffic, the realization of these conditions is of sufficient importance to justify the large expenditure involved. But for this it is necessary, as already stated, that there should be a very large amount of traffic; if this is not the case, the great length the yard is bound to have owing to the arrange-

ment of the different sidings (reception sidings, sorting sidings, marshalling sidings, departure sidings), not only involves a large capital expenditure, but also makes it necessary to have a large operating staff. The administration of the Bavarian State Railway thinks that such extensive installations are advisable ;

a) If at least 4,000 wagons are dealt with per day;

b) If the sorting has to be effected for a large number of stations in a large number of different directions; and if, moreover, the work cannot be divided between various yards and if long-distance goods trains cannot be organized.

This administration thinks that although very economic results are obtained with this system at Nuremberg where 4,200 wagons are dealt with every day, this is probably not the case at Aschaffenburg, where there are only 2,300 wagons per day.

At the older sorting yards, the conditions enunciated are generally not satisfied, and could not be realized without excessive expenditure on account of local hindrances and of the difficulty of giving these yards such a large extension.

Thus there are a number of French sorting yards where there is only one large sorting gridiron with a saddle-back and waiting and departure sidings at each end. The sorting and marshalling operations are carried out at each saddle-back.

The result is that it is necessary to interrupt the sorting operations at one or the other saddle-back each time a train made up on a track of the sorting siding starts.

4° *Please enclose in your answer plans of the yard or yards best satisfying the two conditions* 1° *and* 2° *above. Please also state what area is occupied by these yards, what the total length of track is, and how many cars are dealt with every twenty-four hours; each car arriving at the yard to be counted as one unit only.*

We give below, together with some particulars supplied to us by the different railway administrations, a list of the stations described as best satisfying the two conditions previously mentioned; namely :

1° Continuity and uniform direction of movement during shunting operations ;
2° Elimination of all interruption to shunting operations.

GERMANY.

Brockau yard, Silesia.

Area : 87·9 hectares (217·21 acres).

Length of track, main-lines	11·750 kilometres	(7·301 miles).
Subordinate lines	87·852 —	(54·590 —).
Total. . .	99·602 kilometres	(61·891 miles).

420 switches.
4 block-system signal cabins.
11 shunting cabins.
7 traversers.
4 saddle-backs.
5,500 wagons per twenty-four hours, at busy times 6,500.

Wilhelmsburg yard, near Hamburg.

Area : 55·4 hectares (137·40 acres).
Length of yard : 2·770 kilometres (1·721 miles).

Length of track, main-lines	10·650 kilometres	(6 618 miles).
Subordinate lines	31·710 —	(19·704 —).
Total. . .	42·360 kilometres	(26·322 miles).

240 switches.
3 block-system signal cabins with 57 levers.
3 shunting cabins with 67 levers.
10 switching stations with 129 levers.
5,500 wagons per day.

Rothenburgsort yard, near Hamburg.

Area : 41 hectares (101·32 acres).
Length of yard : 2·440 kilometres (1·516 miles).

Length of track, main-lines.	7·0 kilometres	(4·350 miles).
Subordinate lines	49·5 —	(30·758 —).
Total . .	56·5 kilometres	(35·108 miles).

5 saddle-backs and 1 rail-brake.
255 switches.
5 block-system cabins with 89 levers.
12 switching stations with 145 levers.
1,800 wagons per twenty-four hours.

Hausbergen yard, near Strasburg.

Area : 94 hectares (232·29 acres).
Length of station : 4 kilometres (2·486 miles).
Length of track : 85 kilometres (52 818 miles).
7 block-system cabins with 66 signal levers, 75 route levers and 298 switch levers.
4,500 wagons per twenty-four hours.
Capital cost : 23 million francs (£920,000).

*

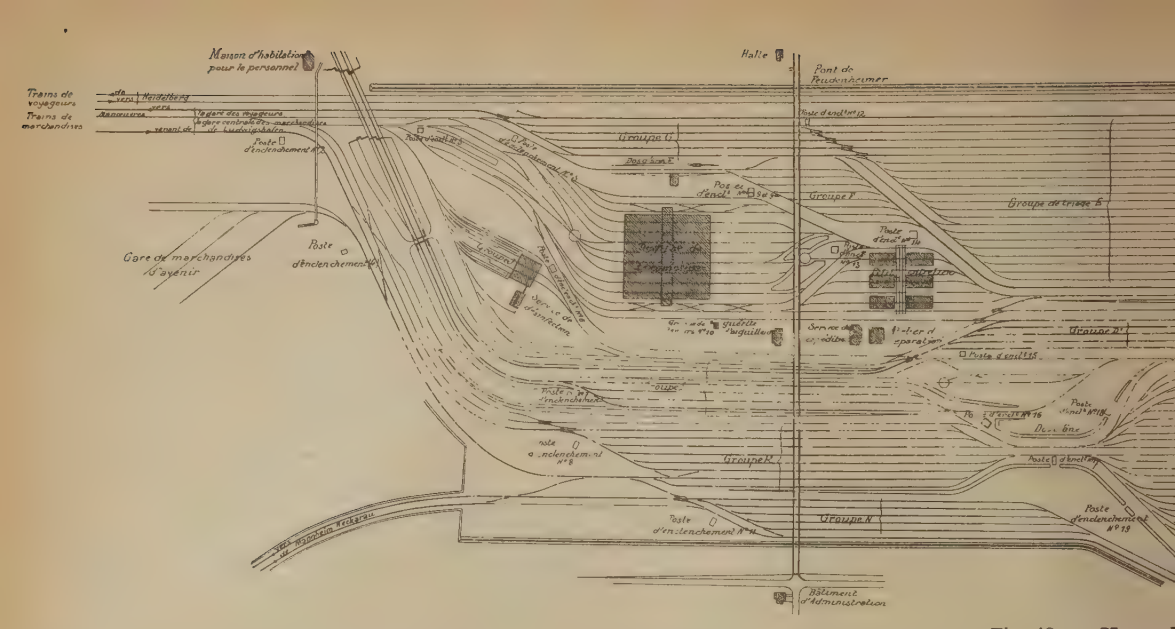

Fig. 12. — **New sh**

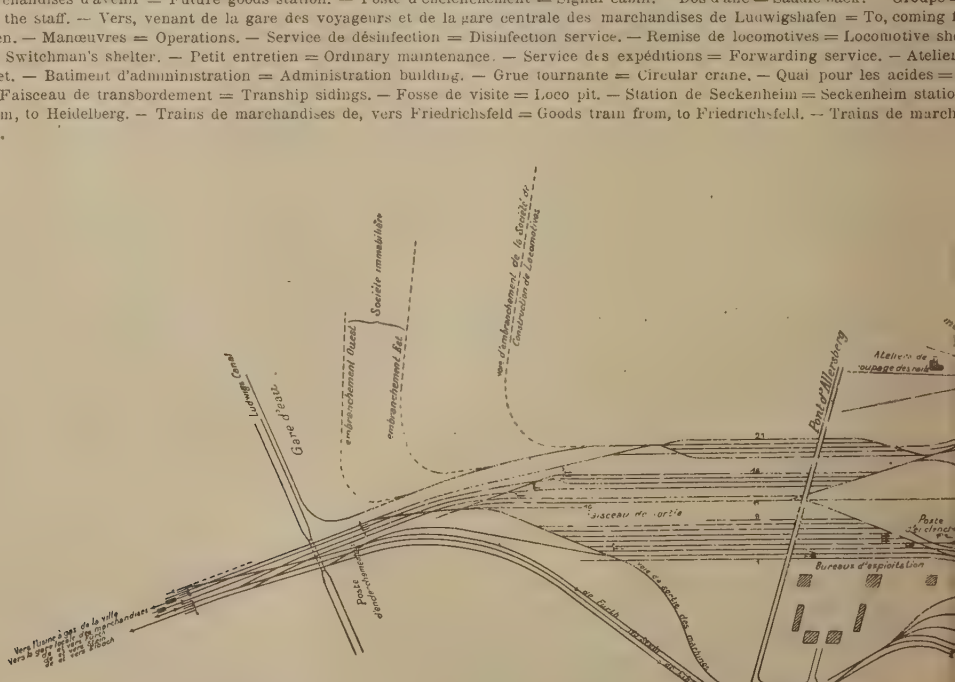
Explanation of French terms of figure 12 : Halte = Stopping place. — Pont de Feudenheimer = Feudenheimer bridge. — Trains de voyageurs = Passenger trains. — Gare de marchandises d'avenir = Future goods station. — Poste d'enclenchement = Signal cabin. — Dos d'âne = Saddle-back. — Groupe = = Dwelling house for the staff. — Vers, venant de la gare des voyageurs et de la gare centrale des marchandises de Ludwigshafen = To, coming f station at Ludwigshafen. — Manœuvres = Operations. — Service de désinfection = Disinfection service. — Remise de locomotives = Locomotive sh Guérite d'aiguilleur = Switchman's shelter. — Petit entretien = Ordinary maintenance. — Service des expéditions = Forwarding service. — Atelier de triage = Sorting set. — Batiment d'administration = Administration building. — Grue tournante = Circular crane. — Quai pour les acides = Tranship building. — Faisceau de transbordement = Tranship sidings. — Fosse de visite = Loco pit. — Station de Seckenheim = Seckenheim statio = Passenger train from, to Heidelberg. — Trains de marchandises de, vers Friedrichsfeld = Goods train from, to Friedrichsfeld. — Trains de march from, to Schwetzingen.



The Nuremberg shunting yard is on a continuous incline extending from the reception sidings to the departure sidings. First come the reception sidings, then the sorting sidings, and then the marshalling sidings, forming a gridiron. From the latter the wagons are taken in the order desired to the departure sidings where the train is completed.

It is only when there is a strong head wind or when it snows, that the wagons are taken from the reception sidings up the saddle-back in order to give them the necessary velocity.

Circular cranes and travelling cranes are very generally used where goods are unloaded. Inside covered premises, in France, the cranes known as Nepveu cranes are frequently used, which run on overhead rails at right angles to the tracks; the

bottom end is supported on the surface of the ground. These appliances are generally operated by hand.

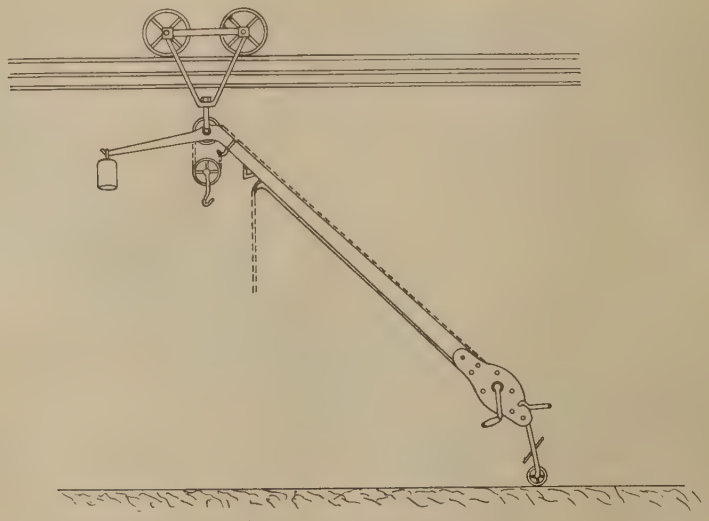

Fig. 15. — Nepveu crane.

Steam or electric traversers are also used at many yards.

Finally the use of electric capstans, with return barrels, tends to become and more general for moving the wagons about on sidings and turn-tables. These capstans were at first designed to develop a maximum tractive effort of 800 kilograms (1,760 lb); now they are generally designed for one of 1,000 to 1,100 kilograms (2,200 to 2,425 lb.). This not only enables longer train-sections to be operated, but makes the starting certain, even if the track is in bad condition, or is covered by sand or mud, as sometimes happens at very busy stations. The capstans can be of two different types : direct acting, when the electric motor is fixed direct to the shaft of the barrel, or indirect, when the motor acts on that shaft through gearing. The direct-acting type, which is only used when the electric energy is supplied in the form of continuous current, allows the barrel, when the current is cut off, to turn in either direction and so makes return movements possible. This may be of advantage if the wagons, by virtue of the speed acquired, run beyond the capstan. This type of capstan also seems to act more gently on the rope, which will consequently become less worn. But present experience does not yet enable us to be certain on this point. The wear of the rope is moreover one of the most important factors affecting the cost of operation of the capstan. A compound rope, that is to say a rope made of steel wire laid round a hemp core, appears to give the best result.

b) At yards where there are several floors (cranes, lifts, travelling endless belts, mechanically operated trucks, etc.).

Many yards with several floors are to be found in England: they also commence to be used at several large French yards. Special instances are the Paris Ivry and the Bordeaux Bastide yards on the Orleans Railway.

The New Bridge goods yards at Newcastle (North Eastern Railway) deserve special mention.

The building is made entirely of reinforced concrete and includes a basement, a ground floor, two upper floors and a terrace. The equipment includes 1-ton electric cranes, a wagon hoist which can raise 20 tons and lower 30 tons, 1-ton lifts, capstans and an electric traverser. The electric cranes are suspended cranes which in addition to their movement of rotation can be displaced transversely along rails; these rails are fixed to a rolling bridge. Thus the field of operations of these cranes is extensive. In the basement, in addition to cranes similar to those just described, there are two cranes revolving about pillars, at the bottom on a rolling path made on the ground, at the top on a rolling path hung from the ceiling.

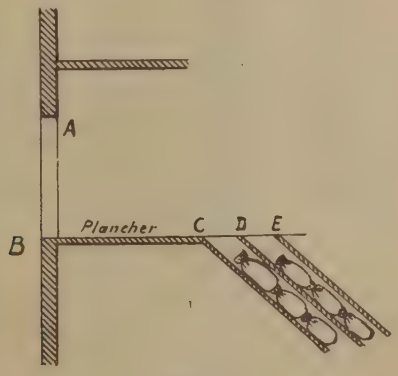

Fig. 16.

Explanation of French term : Plancher = Floor.

This yard also has a storehouse for corn, where the sacks are stored in inclined corridors. They are brought by means of electric cranes through the windows AB and taken to CD, DE, where there are the traps giving access to the corridors. These corridors are very numerous and arranged in such a way at the bottom that an employee can, by operating the appropriate traps, load a wagon with sacks coming from any given group of corridors.

Among the electric equipment of such buildings having several stories, we may also mention a barrel-lift which is in use at the Paris Ivry station (Orleans Railway).

*

and gives very good results. This barrel-lift, of which we give a general view and also details, consists of an endless chain operated electrically, which carries at intervals supports, formed of a kind of comb, the teeth of which are of an angular shape ABC.

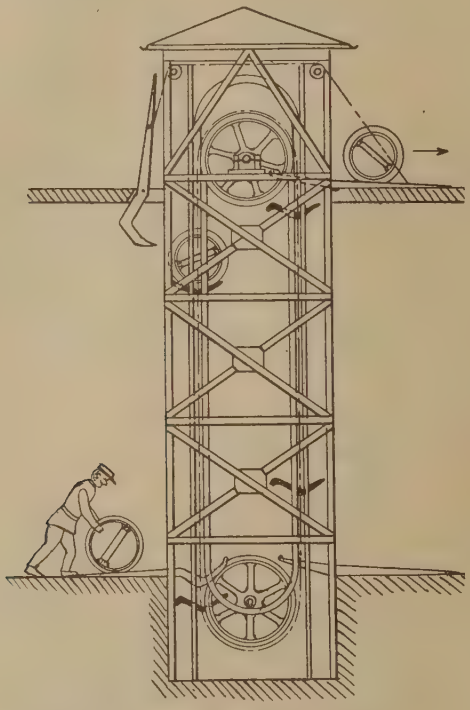

Fig. 17. — Continuous barrel-lift. General view.

The barrel is brought to the end of a platform EF which also has teeth, corresponding to the empty spaces in the combs ABC. As it travels, the comb ABC passes through the platform end and raises the barrel which has been placed there. Two arms BG and BH which are fixed to the comb, ensure its guidance, so that it takes a movement of translation. With this object in view, the roller G follows a groove formed by two vertical parts connected at the top and bottom by semicircles; the roller H also follows a circular groove at the top and bottom, namely at those places where the guidance of the one roller G would not suffice.

This lift has a considerable capacity; it provides from 80 to 100 empty spaces per hour. It can also be used for packages of all kinds, provided their shapes and dimensions are within the limits determined for each given type.

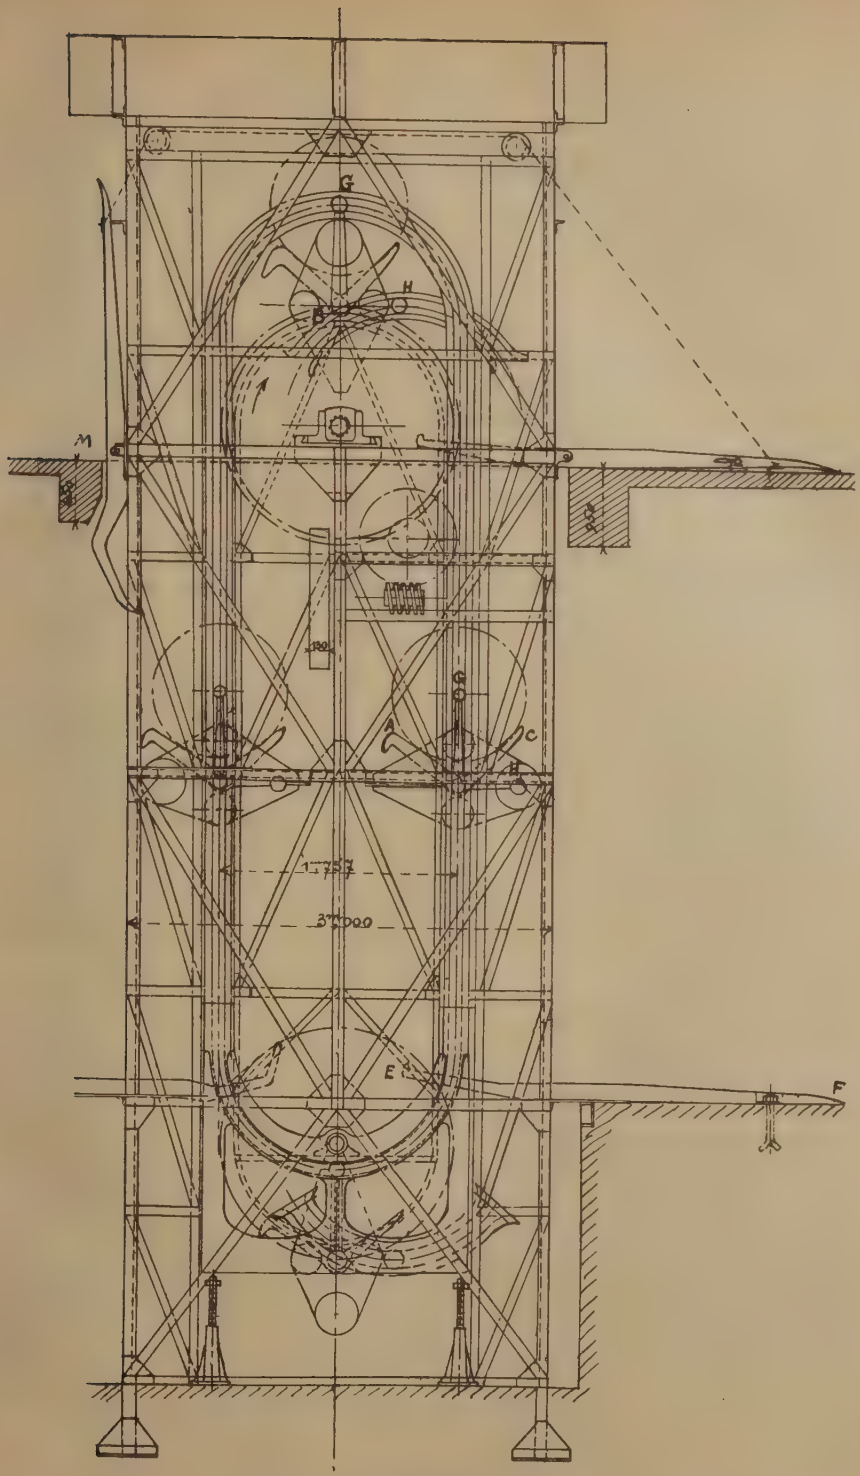

Fig. 18. — Continuous barrel-lift. Details.

Finally, we will mention the mechanical sorting of the parcels despatched from Paris-Austerlitz station by means of endless belts and shoots which has been described in detail in the February and March 1902 numbers of the *Revue générale des chemins de fer*.

CONCLUSIONS.

Large passenger stations.

The preceding information leads us to conclude, as regards large passenger stations, that in order to obtain the maximum working capacity, combined with safety of working, it is advisable in the first place to divert from them everything connected with the local goods and parcels services. It is equally advisable to concentrate the suburban service on certain tracks which are in principle reserved for it; but to utilize at certain hours or on certain days, where one of the two traffics, suburban or main line, becomes of preponderating importance, either the main lines for the suburban service, or the suburban lines for the main-line service. The establishment of large scissors crossings at the entrance of stations which makes it possible to receive a train coming from any direction on any of the tracks tends to become general and seems to be an excellent means for increasing the working capacity. The use of power-operated signals and switches, which can be set easily and quickly, and the use of which tends to become general, makes it possible to utilize these connections under the best conditions. It is finally an advantage to have in front of the different platforms tracks making it possible to change locomotives quickly or to alter composition of trains quickly. A set of marshalling sidings near the station, and connected with it by independent tracks, is also a very useful addition to the installation.

When the local conditions allow it, it is as a rule of advantage to adopt either the type of a station with floors, or the type of mixed station, that is to say including tracks at two different levels. The ground is then utilized better, the passengers can be more easily distributed among the various platforms, and the luggage service can be carried out with much less inconvenience to the passengers.

The use of mechanical appliances for handling the luggage is much to be recommended, and, at stations with floors, the use of elevators to save the public the mounting of stairs, appears to be an important improvement, particularly when those elevators are of the continuous-action type.

It has to be added that it is rather exceptional to have to build a whole new large passenger station. It is much more usual to have to modify or enlarge an existing station; one is then hindered by local difficulties from applying the principles we have expounded, except to a limited extent.

Large goods yards.

Shunting yards, on the contrary, can as a rule be built in the open country and constructed to suit the purpose they are intended for, without having their design influenced by local conditions foreign to the working conditions of lines which are to be provided for.

Such yards, it seems, should in all cases include three sets of sidings for : the standing after the entry, for the sorting and finally for the marshalling and standing before the start, of the trains to be dealt with. The length of those sidings depends on the length of the trains, and their number, on the density of the traffic.

When the yards have to provide for a very busy traffic, other sidings of less importance are added for the geographical sorting.

Finally these can all be doubled, so as to have two distinct complete sets, one for the one direction and the other for the other.

It is a great advantage to arrange these different sets as well as the running lines, in such a way as to obtain a continuity of movement in the shunting operations and to eliminate any interruption of these operations owing to the arrival or departure of trains.

Shunting yards cannot practically be built with a continuous incline unless the ground has a natural slope; and in most cases it appears preferable to have saddle-backs. The skid seems to be the best appliance for stopping wagons.

The mechanical handling of the goods or wagons in the buildings and near the buildings, by means of hand cranes or electric cranes, of electric capstans, of lifts, etc., tends to become developed and constitutes an important improvement. It results in the more frequent use of buildings with several floors.

REPORT N° 3

(America)

By H. A. JAGGARD,

SUPERINTENDENT, PENNSYLVANIA RAILROAD.

Questions were sent to thirty-seven American railroads. In the selection of the roads to be interrogated effort was made to take such roads as were known to have made progress in the directions indicated. Replies were received from the following roads :

Argentine Republic.

Buenos Aires Great Southern Railway.
Buenos Aires & Rosario Railway.

Canada.

Grand Trunk Railway.

United States.

Atchison, Topeka & Santa Fe Railway.
Atlantic Coast Line Railroad.
Baltimore & Ohio Railroad.
Baltimore & Ohio Southwestern Railroad.
Boston & Albany Railroad.

*

Chicago & Alton Railroad.
Chicago, Burlington & Quincy Railroad.
Chicago, Milwaukee & St. Paul Railway.
Chicago & North Western Railway.
Chicago, Rock Island & Pacific Railway.
Chicago & Western Indiana Railroad and the Belt Railway of Chicago.
Cleveland, Cincinnati, Chicago & St. Louis Railway.
Delaware & Hudson Company.
Denver & Rio Grande Railroad.
Erie Railroad.
Illinois Central Railroad.
Lake Shore & Michigan Southern Railway.
New York Central & Hudson River Railroad.
Northern Pacific Railway.
Pennsylvania Lines West of Pittsburgh.
Pennsylvania Railroad.
Philadelphia & Reading Railway.
Pittsburgh & Lake Erie Railroad.
Southern Pacific Railroad.
St. Louis & San Francisco Railroad.
Union Pacific Railroad.

Uruguay.

Central Uruguay Railway of Montevideo.

The data and conclusions set forth herein rest chiefly on the information thus obtained.

A. — CONCERNING LARGE PASSENGER STATIONS.

Question 1. — *Have you adopted any special arrangements in order to increase the working capacity of your stations and to insure the safety of the shunting operations?*

Much thought has been given to this problem. It has been forced upon railroads and terminal companies by the rapid growth of cities, such as Boston, New York, Philadelphia, Washington, Pittsburgh, Chicago, St. Louis, and others. Various solutions or partial solutions have been reached. The question is intimately associated with the development of electrical systems of movement, whether by electric locomotives or by the multiple unit system.

The condition of some of the roads (more especially in the West and South, where

the population is less concentrated) is indicated by the answer of the Chicago, Burlington & Quincy Railroad :

No. The conditions under which passenger traffic is handled on the Chicago Burlington & Quincy Lines is entirely different from that to which the questions herein given apply. On the Burlington Lines the larger percentage of the business is freight; and while doing a large passenger business for its territory, it is at no point so congested as to call for special passenger handling facilities.

The Union Pacific Railroad says :

Aside from the use of slip switches ond two leads at each end of a group of 6 to 8 tracks, we have not adopted any special arrangement, but have made designs which require the handling of baggage by means of subways, with elevators to carry the baggage to the track level, which, to a certain extent, reduces switching. We have also made designs having the passenger tracks in pairs, with subways for the passengers to reach the platforms between the tracks without crossing them, thus saving considerable switching.

QUESTION 1-*a*. — *Are the tracks for main line trains grouped together in a set separate from the set of tracks used for suburban trains ?*

The general answer to this question is " No ". Suburban traffic on a large scale is a comparatively late development in many localities. It appeared too late to affect designs made twenty-five to forty years ago. In designs of this date, however, the Operating Departments have adapted the use of old track lay-outs to effect more or less of a separation. Many modern stations, however, show a separation of suburban traffic from through, or main line, traffic. The most complete illustrations reported are found in the new 42nd Street Station of the New York Central & Hudson River Railroad, in New York City, and the New York Terminal Station, Pennsylvania Railroad. The Union Station, Washington, illustrates the same principle.

QUESTION 1-*b*. — *Are the suburban tracks arranged so as to reduce shunting operations to a minimum ? Have you, for instance, adopted, as the solution, and loops at certain stations, as at Boston Station (U. S. A.) ?*

The new 42nd Street Station of the New York Central & Hudson River Railroad in New York City shows the use of the loop solution worked out very thoroughly and consistently. The design shows :

An express level, for the handling of main line trains; on this level there are five loop tracks, which are served by three loop platforms. (Radius of the loop, 329 feet.) Inbound trains will move to the loop platforms, discharge their passengers, pass around the loop,

and move to convenient storage yards, or to passenger platforms within the loop, where they will wait until the scheduled times of departure. In this way the loop platforms handle the inbound business, and the tracks on the inside of the loop the outbound business. There are 28 outbound tracks situated within the loop, which are served by 13 platforms, including two mail and baggage platforms. In addition there are 13 storage tracks which may on occasion be used for departing tracks. These tracks have five low platforms.

A suburban level, which has four loop tracks served by three platforms, these for inbound trains. For out-bound movements there are 10 tracks with 6 platforms within the loop. The suburban level shows a 2-track loop. It is the intention to move suburban business chiefly in multiple unit cars.

By the arrangements set forth above the shunting operations are enormously reduced, as compared with the present arrangement, by which main line trains have to be moved by shifting power about five and one-half miles to the Mott Haven cleaning yards.

The New York Terminal Station of the Pennsylvania Railroad shows modern arrangements as regards reduction in shunting operations and the securing of safety. The problem here is to take care of the suburban business from Long Island and from the State of New Jersey, as well as the through business moving between New England and the South and West. The Long Island business will be cared for by platforms 1 and 2 and by tracks 1, 2, 3 and 4, on the north side of the station. The New Jersey business will be cared for by platforms 9, 10 and 11 and by tracks 16, 17, 18, 19 and 20, at the south side of the station. The through business will be handled from the middle tracks and platforms.

In the older stations, various arrangements have been adopted for reducing the shunting operations. At the South Terminal, Boston, the loop which was built some years ago is not yet in use, since the necessary electrification of outlying territory has not been completed. The track lay-out, however, is such as to permit the engine of an inbound train to cross over (after being released by having its train pulled away by another engine) and couple to the coaches of another suburban train which has recently arrived. The engine of the latter train in turn moves out a short distance, crosses over, and couples to other recently arrived coaches. The engines under this system must run tank first in one direction. They are equipped with cow catchers at both ends, and the tenders are of such construction as to allow a clear view for the engineman an fireman. The New York, New Haven & Hartford Railroad uses this method for trains within the ten-mile limit. The Boston & Albany Railroad employs this method in a zone 11 miles long. The quickness of operation is shown by the following figures :

7·38 a. m. train spots with 7·45 a. m.;
7·39 a. m. — — 7·51 a. m.;
7·45 a. m. — — 7·53 a. m.;
7·46 a. m. — — 7·55 a. m.;
7·47 a. m. — — 8·15 a. m.;
7·53 a. m. — — 8·07 a. m.; etc.

For instance, on the arrival of the 7·38 a. m. train the passengers are discharged, outgoing passengers are received, an engine from an adjacent track couples to these coaches, and the train pulls out at 7·45 a. m. The engine which brought in the 7·38 a. m. train goes out with the 7·51 a. m. train, etc. The quickest movement made by the Boston & Albany Railroad is the one in which the engine which brings in the 8·27 a. m. train takes out a train at 8·40 a. m.

The Union Station of the Terminal Railroad Association, at St. Louis, shows a unique arrangement of tracks which forms a double wye. Its advantage is thus described :

Attention is called to the general arrangement of handling passenger trains at Union Station, St. Louis, the method being to back the train into the station, and, after so doing, return on the opposite leg of wye. By this process the entire train is turned and it is set off intact in the coach yard. This method results in a great saving of damage to equipment made necessary where cars must be separated and their reverse position in train provided for when departing. I believe the Union Station at St. Louis is the only one in the country where this meihod of handling trains is persued.

Other replies follow :

Pennsylvania Railroad.

No. At Broad Street Station inbound suburban trains are utilized for outbound by permitting the locomotive and train to remain in the shed and usind the cars for trains leaving within ten minutes.

Chicago, Burlington & Quincy Railroad.

All shunting is done in a yard apart and entirely separate from the station.

Union Pacific Railroad.

We have no large stations requiring special arrangement ol tracks to expedite the changing of locomotives and cars, and none necessitating the use of end loops.

In general, the older large stations show tracks arrangements which permit quick movement from any track to any other track by double and single ladders, slip switches, etc., which command entrance to the station. This arrangement is characteristic of American practice at this time, rather than loops or special devices. With the unquestioned increase in electrification, however, the loop device will doubtless be more generally adopted.

QUESTION 1-c.— *How are the tracks arranged so as to make it possible:* I) *to change locomotives quickly;* II) *to add or take off carriages;* III) *to make up trains or bring to the platform trains made up on a special set of sidings?*

I) In the South Terminal, Boston, the track arrangement for allowing the quick changing of locomotives has already been described. The Union Station, Washington, shows for the high level track an arrangement of them in pairs, with a crossover connecting the two tracks constituting a pair. By this arrangement, a coach or parlor car which may have to be added to a train and occupy a particular position therein may be so placed by previously locating it against the bumping block; if it is determined at the last moment that it is to go in the train, a portion of the train is set over by the crossover to an adjacent track, the remainder of the train backs against the coach in question, then pulls forward, crosses over, couples to the remaining portion of the train, returns to the original track, and is reday to start.

The New York Central & Hudson River Railroad replies to questions I, II and III:

Coach yards and engine tracks as near as possible to passenger yard, and an extensive arrangement of slip switches is used to make switching movements as short as possible.

The Baltimore & Ohio Railroad replies:

c) I: Either a crossover or spur track is placed immediately ahead of where the locomotives, after pulling into the station, come to a stop. The locomotive is cut off from the train and run ahead, either on the same track or an adjoining track, or on a spur track, and the locomotive to be attached is backed down from an adjoining track to that occupied by the locomotive that has completed its run.

c) II: The same arrangement is resorted to as for locomotives, except that the lead is placed so as to clear the rear of the longest train, either by a series of crossovers or a spur track on which a shifting engine stands awaiting the arrival of the train. If the coaches are to be attached they are placed ahead of this engine and pushed up to the rear of the train immediately upon its arrival: if coaches are to be detached, the engine simply pulls in over the crossover and takes away the coaches that are to be removed.

c) III: Special coach yards are provided for cleaning and classifying, and which are accessible to the train shed or platform, each track being accessible to every other track through a series of crossovers or slip switches, or both, as may best suit the local conditions.

The Grand Trunk Railway replies:

The only means used so far is to have the tracks lead out to a general lead or ladder track, with separate switches to coach yards.

The Illinois Central Railroad reports :

Our suburban tracks of Randolph Street, Chicago, six in number, are connected at either end by a system of switches, manually handled, and engines of incoming trains are cut off immediately on arrival and moved to the roundhouse as soon as the outbound train which uses that equipment is taken off the track, which is usually in a very few minutes. Suburban trains between 7 and 10 a. m., when the inbound movements are heaviest, are drawn immediately from the station by a switch engine and stored on long tracks, without switching, as the trains remain intact and are not switched or the relative position of the different cars changed. Between 5 and 7 p. m., when the business is outbound, these trains are placed on the various tracks by a switch engine, after which the road engines are coupled on to them.

The Chicago, Rock Island & Pacific Railway reports :

I : In Chicago, which is a head-on station, when a suburban train pulls in an engine couples on to the other end and is ready to start out; then the first engine pulls on to a siding near by and couples on to the next train.

II : No provision made to add extra cars to a train at La Salle Street Station, Chicago, but arrange to do it at other places — a turntable should be built and a track for private cars.

III : Have designated certain sidings outside of the station on which trains made up are ready to back into the station at any time.

The Buenos Aires Great Southern Railway replies :

At terminal stations the tracks are arranged in pairs with crossovers enabling engines to run around other trains for a return trip within a few minutes, when necessary. Connections between these lines and the yard enable the operations mentioned in questions I, II and III to be carried out.

As stated, in the older stations the practice is to use the entering system of ladders for the movement from any one track to any other track. In stations, however, where the number of tracks exceeds a dozen, the length of the ladder is such that in certain instances the movement takes more time than the station operations can advantageously spare. A locomotive of an inbound train cannot be released, generally speaking, until its train has been pulled out of the shed, either by a shifting engine or an engine which moves the cars to the next station en route. Generally speaking, the adding or taking off of coaches is done by shifter engine, which must come from outside of the shed.

A very interesting solution of the track arrangement pertaining to Question III is found between the Sunny Side Yard, on Long Island, and the New York Terminal Station of the Pennsylvania Railroad. Here the multiple unit system equipment used for the Long Island suburban business must be moved from the station through a tunnel under East River to Sunny Side Yard on Long Island for purposes of storage cleaning, etc., and this must be combined with the movement out of the station of the through equipment with electric locomotives to the same Yard for

the same purposes through a parallel tunnel. The division of the currents of movement, which is effected by a skilful separation of grades and a loop entrance into Sunny Side Yard, results in a quite complicated track plan, which is appended to this report (fig. 4). The development of proper facilities in connection with the electric transportation is very consistently worked out.

Question 1-*d*. — *Have you any stations with separate floors in which the tracks are, either all or in part, either on an upper floor or in a basement, the ground floor being used for different offices (enquiry offices, booking offices, luggage offices)?*

Quite a number of stations are found in which the tracks are, either all or in part, on an upper floor or in the basement, and where the ground floor is used for the different offices.

In the case of a mixed arrangement, that is to say, when some of the tracks only are at another level than the ground floor, which tracks are at that level and which tracks are on the ground floor?

Few cases of a mixed arrangement of tracks as described are found; in such instances, however, the ground floor is usually used for the main line or through tracks, and the suburban level is in the basement.

In the case of stations with separate floors, how are the different services distributed between the ground floor and the other floor?

Where stations have separate floors, the offices are usually distributed between the two floors according to space and utility. Effort is made to avoid duplication.

What circumstances : topographic location, difficulty of widening, etc.,—have led to the adoption of separate floors?

The adoption of separate floors has resulted in parge part from the requirement of cities that tracks be elevated or depressed to eliminate grade crossings and avoid smoke. Supplementary cases are : Topographic conditions, high value of real estate, enormously increased passenger business.

What advantages do you consider this arrangement to have to make up for the increased amount which as a rule such a station costs to build and run?

The rapid increase in wealth of the country has brought about a heightened demand for luxury and accomodation in all lines. The railroads, in building elevated stations, have been able to consult and gratify this growing taste by vastly

improved architecture and interior arrangements — as expressed in lighting, heating, ventilation, sanitary conditions, and many other forms of public comfort. In a number of instances, this development has taken the form of high public spirit.

Other phases are shown in the following typical replies of the railroads :

New York Central & Hudson River Railroad.

Yes. See plan of Grand Central Station, New York City (fig. 2).

At some stations the ground floor is used for the waiting room and offices, and the tracks are at a higher level and are reached from the waiting room by a transverse subway under the tracks. At other stations, tracks at lower level are reached by stairways.

Main tracks on te ground floor level.

By stairways and inclines.

Cost of land; elevation of subway lines; necessity for eliminating grade crossings; natural differences in grades in railways and highways

Convenience to the public; compactness; facility of operation.

Pennsylvania Railroad.

Broad Street Station, Philadelphia; Washington; Jersey City; Harrisburg; New York (under construction [fig. 3]).

Topographic and limited available space.

Additional floor space. At Harrisburg enabling the throwing of bridges for use of passengers and baggage across track.

Philadelphia & Reading Railway.

At Terminal Station, Philadelphia, tracks and waiting rooms are on the second floor. Ticket offices and baggage rooms are on the first floor.

Tracks are all on the same level.

Elevators are used from first to second floors.

At terminals in cities, it is frequently necessary to place tracks above street levels, baggage is handled from street level making it necessary to separate the floors, placing baggage room on street level and tracks above street level.

No advantages other than those stated.

Baltimore & Ohio Railroad.

The stations having separate floors are : Union Station, Washington, D. C.; Camden Station, Baltimore, Md.; Wheeling, W. Va.; Columbus O.; Youngstown, O.; and Wilmington, Del.

Camden Station, Baltimore, has the through tracks depressed and the suburban tracks on the ground floor.

At Union Station, Washington, all trains from northern roads come in on the ground floor and all trains from southern roads on the basement floor.

At these two stations, the ground floor is occupied by waiting rooms, ticket office, concourse, dining room and restaurant. At Camden Station, the baggage room is also on the ground floor, while at Washington it is on the basement floor.

At Wheeling, Youngstown and Wilmington, where the tracks have been elevated to eliminate grade crossings, the waiting rooms, ticket office, baggage room, restaurant, express office, etc., occupy the ground floor of the station. The elevated tracks are covered by train shed, to which the passengers are admitted only on arrival and departure of trains, there being an underground concourse which permits of access only to the platform adjoining the track on which the train is to depart. Or from incoming trains access can be had to the station only by elevators or stairways from the one platform, it being so arranged that passengers cannot cross other tracks.

At Columbus there is a Union Station, and the conditions are the reverse. The tracks are depressed and the station elevated to the level of the adjoining streets. In this instance, the ticket office, restaurant, and waiting rooms are on the first floor of the station, the ground floor being used for baggage and express rooms. An overhead structure spans all the tracks under the station, with gate entrances to the various platforms, so that the passengers have access to only the platform adjoining the track upon which the train arrives or departs.

The topographic conditions govern almost entirely the arrangement of our stations, as where tracks are depressed and the waiting rooms on an elevation with the streets, an arrangement such as at Columbus is thought a good one; whereas, if it is thought necessary in the elimination of grade crossings to elevate the tracks, an arrangement such as at Wheeling or Youngstown is thought to fully meet the local requirements.

The advantages to be gained in arrangements of this kind are, to reduce the danger to human lives by the elimination of grade crossings and arrangements at the station whereby passengers have access to their respective trains without crossing other tracks, the increased speed permitted on account of no grade crossings, time saved and delays avoided account of proper facilities for changing engines and adding to or taking away cars on through trains, saving in watchmen and maintenance of crossing gates at crossings, and the convenience afforded the travelling public.

Chicago, Burlington & Quincy Railroad.

A few stations have separate floors for passengers, but not for trains.
All tracks are on the same level.
To get below or above street level with railroad tracks.

Chicago, Rock Island & Pacific Railway.

At Chicago the trains run on the second floor, the first floor being used for ticket office, dining room, telephone and express room, the second floor being used for all trains. No tracks on any other floor.

St. Louis & San Francisco Railroad.

At St. Louis, all baggage is handled by elevators from the platform level to the basement in order to avoid trucking along passenger platforms, as all tracks stub at the station. The baggage check room, however, as well as main waiting room, all ticket offices, telegraph and telephone offices, parcel check rooms, bureau of information, etc., are located on the main floor on track level. There is a waiting room and a restaurant on second floor for convenience of through passengers waiting for connections, etc.

At Birmingham, Alabama, the waiting rooms, etc. and tracks are on the same level, but access from the station building to track platforms is obtained through subways which take the passengers direct to the trains desired without necessitating the crossing of any other tracks at grade.

At Kansas City the main floor is on the track level, and, as the tracks run through it, it is necessary to cross other tracks at grade to reach any track not adjacent to the building. There is another waiting room and a restaurant on the second floor. This station is to be replaced by a new Union Station in the future.

The topographic conditions, question of present or future grade separation, and in some cases the amount of and peculiar conditions regarding the amount and shape of available ground should be considered in considering the adoption of separate floors. As a matter of safety, passengers should not have to cross tracks at grade to reach their trains, and as a matter of convenience the trucking of baggage on passenger platforms should be avoided where practicable.

Union Pacific Railroad.

In regard to passenger tracks at different elevations, we have no cases which call for this, but if necessary to do it would consider it advisable to arrange the tracks for suburban travel on the most accessible level.

As to the double platforms for quick unloading of passengers, stations with separate floors, travelling inclines, or moving stairways, — we have no terminals which call for arrangements of this kind.

Question 1-*e*. — *Have you adopted the solution of "double platforms" applied more especially on the French Northern Railway at St. Omer and Valenciennes stations?* (*Revue générale des chemins de fer*, November, 1904, May and June 1907.)

The double platforms, found at St. Omer and Valenciennes Stations, are not used. Under American practice the increased capacity would be secured by increasing the number of parallel tracks and island platforms. It is hardly feasible to build American station platforms long enough to receive two trains 500 to 800 feet each, in length, along one continuous platform, and allow between them room for crossover switches of a length 160 to 175 feet from point of switch to point of switch. To permit this, it is assumed — as confirmed by scale — that the Valenciennes platforms are aver one-half mile long and the St. Omer platforms over 1,500 feet long. This arrangement, in certain instances, would require a longer walking distance than the American public would cheerfully endure, except in trolley stations provided for summer business. The actual use of the track arrangement would seem at times to require that a train should be held within the station on the middle track until a platform could be cleared. The American public would become very impatient at this delay, and would not remain in the cars unless they where locked. The advantage secured by the plan in avoiding the crossing of

tracks by passengers and baggage trucks is secured in modern stations by overhead bridges and subways connecting the island platforms with the station building. Again, the American practice of using train sheds from 400 to 700 feet long, covering all the passenger tracks, is against it; the cost of operating three interlocking towers (about $5,000 per annum) for a station for only 13 trains per day in each direction, as at St. Omer, would ordinarily be considered prohibitive. As a whole, the design does not seem to be adapted to American conditions.

QUESTION 1-e-I. — *Have you adopted or experimented with any new arrangements of passenger platforms, so as to expedite the handling of crowds?*

Few experiments are reported. The New York Terminal Station of the Pennsylvania Railroad has high platforms. These platforms are 46 inches above the top of the rail, or about on a level with the car floor. Their use will involve certain changes in the vestibules and platforms of all cars entering the station. The 42nd Street Station of the New York Central & Hudson River Railroad, in New York City, shows high platforms. The Illinois Central Railroad reports:

> We have not adopted any special type of platform, but use a high platform, the elevation being the same as the floor of the car, these platforms being for suburban service only within the limits of the Chicago terminal district.

In general, however, the low platforms are found in American stations.

Have you adopted any new types of passenger cars with special reference to quick unloading?

The Grand Trunk Railway reports:

> For suburban traffic have adopted coaches with spaces at each end where seats are arranged like benches along the sides of the cars, as in the New York Subway cars.

The Illinois Central Railroad operates several trains consisting of cars of which the entire framework is steel. These cars have fixed seats for 100 passengers, arranged in sections transversely of the cars, with two aisles, one on each side of the car extending the entire length of the car, and connecting at the vestibules with end doors. Opening directly from the aisles are 24 sliding side doors, 12 on each side. These doors are placed equal distance apart throughout the length of the car, a door being opposite each section of eight seats. When the side doors are used, the station platforms are about the same level as the floor of the car, and at stations where the platforms are low, the doors and spaces at the vestibule ends of the cars are used by passengers entering and leaving, just as in ordinary end door cars. The doors may be opened separately by the passengers on arrival at the sta-

tion, or may all be closed and locked simultaneously by the guard, who rides within the cars.

Certain other roads show cars where the design has been altered so as to provide wider end doors, and whose steps extend to the low platform level. These show, by experience, an improvement in unloading.

QUESTION 1 *f.* — *Please enclose in your answer plans of the passenger stations on your railway, of each of the types considered (station at one level, mixed station, station with separate floors), which seem to you to satisfy most completely the two desiderata mentioned above; namely to increase the working capacity and the safety of the shunting operations. It would be of interest to state how many reception tracks for passenger trains there are at the stations in question, and how many trains are received on the whole of these tracks during twenty-four hours.*

The table following gives such data as are available as to the number of reception tracks for passenger trains and the number of trains, handled on these tracks in twenty-four hours :

STATION.	Number of reception tracks in station.	Trains handled in 24 hours
South Station, Boston :		
Boston Terminal Company	28	817 received and despatched.
42nd Street Station, New York :

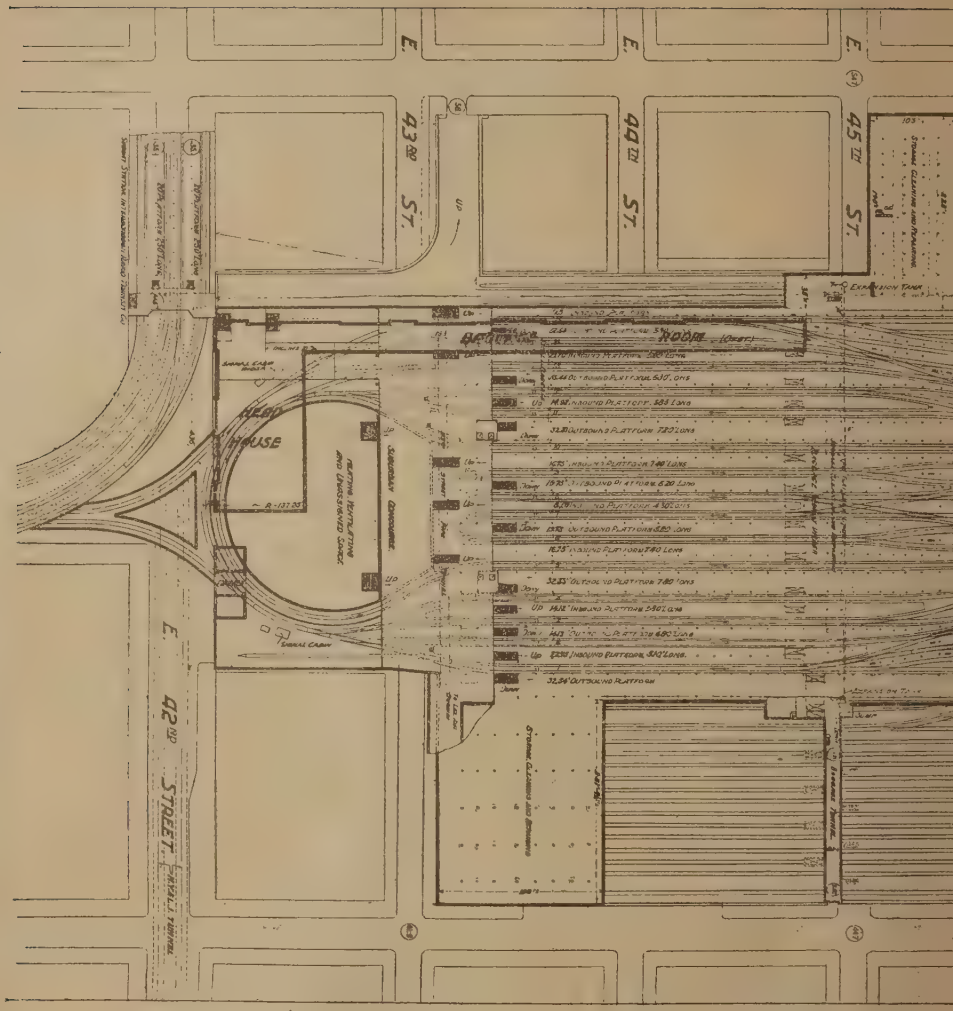

Fig. 2. — Grand Central Station, Ne

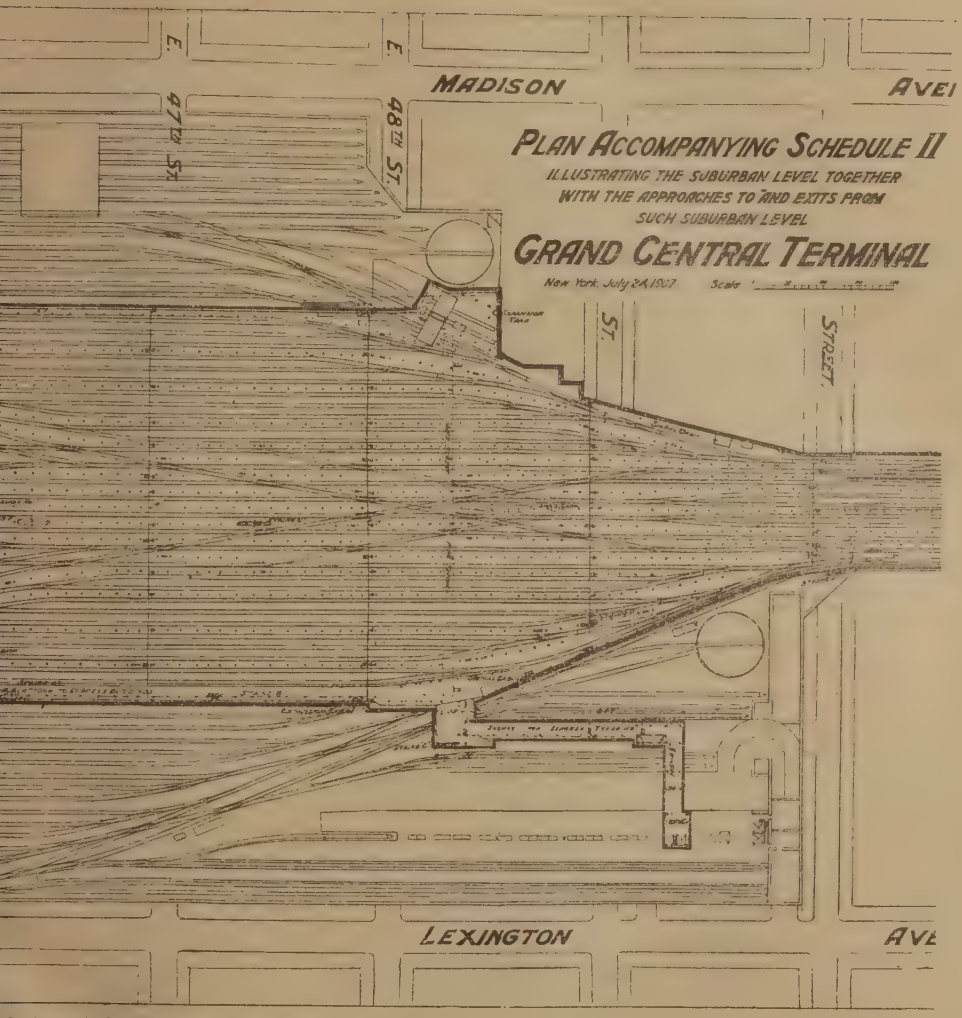
QUESTION 2. — *Please describe the mechanical appliances you have, either at the stations with separate floors, or at the stations at one level.*

a) For the conveyance of luggage (lifts, motor tricycles, travelling endless belts, electric automobiles, etc.).

As a rule, ordinary two-wheel and four-wheel trucks are used to convey baggage on a level. Wire rope haulage elevators (electric and hydraulic) and plunger eleva-



rk Central & Hudson River Railroad.

tors are used for moving baggage between levels. Electric baggage automobiles are in use at Jersey City, Broad Street Station, Philadelphia, Union Station, Pittsburgh — stations on the Pennsylvania Railroad — and Union Station, Washington. The Pennsylvania Railroad electric baggage trucks are described as follows :

Length over end standards, 12 feet; height of floor, 30 inches; width, 44 inches. Carrying capacity, 200 cubic feet (4,000 pounds), equivalent to 20 average size trunks.

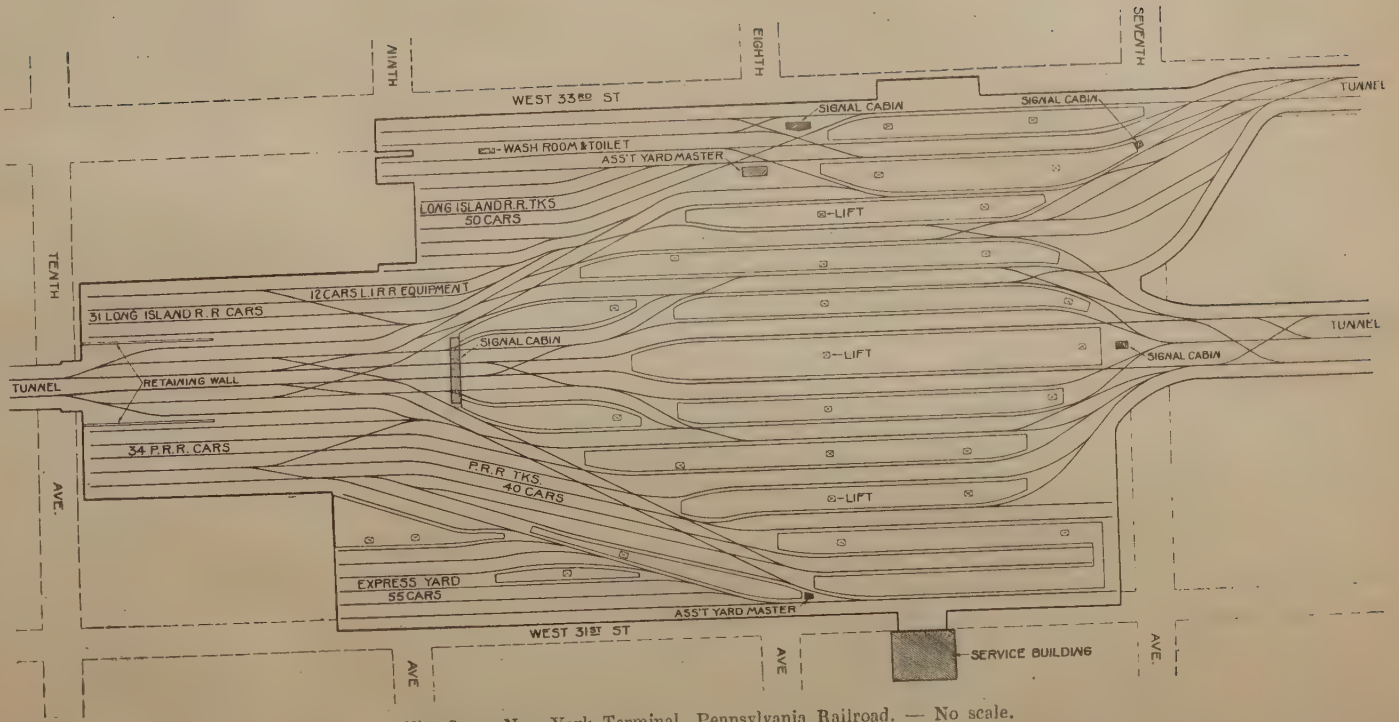


Fig. 3. — New York Terminal, Pennsylvania Railroad. — No scale.

Weight of truck, 2,590 pounds. The truck is provided with small platforms, one being mounted on each end; either of them may be folded up out of the way when not used. These platforms are for the use of the driver.

A steering lever and controlling handle socket are mounted on each end of the truck. The braking is done by brake pedal on the platform. The steering is done by all four wheels, which allows turning on a small radius. The controller provides for three speeds, the first to relieve the motor of shock, and the second and third being running speeds. The speed in the second position is from 4 to 5 miles per hour, and in the third position from 5 to 7 miles per hour.

The motor is of the four-pole series type, with fields arranged for series or series parallel control, and is flexibly mounted on the countershaft housing, and is powerful enough to handle the truck with a load of 4,000 pounds up a 6 per cent grade.

The battery is composed of 12 cells of 15 plates each, having a capacity of 196 ampere hours. The arrangement of the battery permits ready removal and replacement.

The wheels are of the artillery type; the rim is made in two sections, one of which comprises the rim proper, while the second section comprises the driving gear on the two wheels at the motor end of the truck. This section, however, is bored out to form a bearing for the internal expanding brake on the two wheels at the trailing end of the truck. The gear reduction between the motor and the driving wheels is 25 to 1. The driving wheels are mounted on steering knuckles similar to those used on the front axles of automobiles.

The construction is best shown by the figures 6 to 8.

Figure 6 : Shows the driver in position, with the steering handle turned to the right.

Figure 7 : Shows an assembled cam shaft and motor unit; the universal pinions are shown at each end of the housing, while a cyclometer is shown on the housing above the motor.

Figure 8 : Is a view of the chassis, showing the arrangement of the battery suspension, controller, and motor drive.

In the new Grand Central Station of the New York Central & Hudson River Railroad at 42nd Street, New York City, horizontal moving platforms will be used for the conveyance of baggage. These platforms will have a speed of about 200 feet per minute. They will be placed between the loop tracks on the express level, and will be three in number, serving five loop tracks; baggage will be unloaded directly from the cars of incoming trains to these platforms, which will move them to the distributing platform in the baggage room. It is not the intention to use these platforms for outgoing baggage; that will be handled by automobile trucks raised to the platform level by elevators located approximately ten car lengths from the bumping post.

Question 2-*b*. — *For the conveyance of passengers (lifts, travelling inclines, moving staircases, etc.)?*

The common practice is to use elevators of the plunger type or rope haulage. Moving staircases have been shown in recent designs, but so far have been little utilized.

Brief descriptions of the new Terminal Station of the Pennsylvania Railroad, in

*

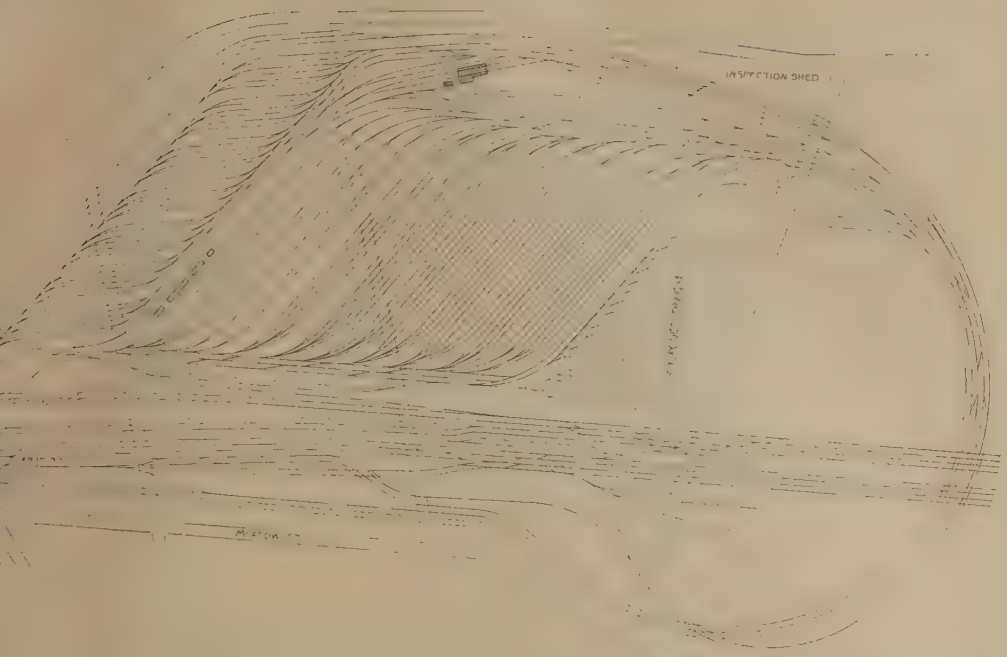
Fig. 4. — Sunny Sid

New York City, and the Union Station, Washington are given. The remodelling of the Grand Central Terminal of the New York Central & Hudson River Railroad, in New York City, on an elaborate scale is still in progress.

New York Terminal Station.

Pennsylvania Railroad.

This station is unique among the railway stations in the world, and its design will probably have much influence on the type of future stations in America. The introduction of



Railroad. — No scale.

electricity and the consequent elimination of the smoke nuisance has made it practicable to build a plant of monumental and durable character. The depression of the tracks to the level of 40 feet below the street surface, necessitated by the tunnel entrances, has presented a new problem in architectural design. The architects have endeavoured to give to the exterior of the building a familiar railway expression, and have been guided, as well, by the idea of expressing the magnitude and dignity of its position in a great city, not only as a distributing point for transportation, but also as a monumental gateway. This result is believed to be obtained by the simple, severe, and dignified character of the exterior, as particularly illustrated by the monumental colonnaded treatment of the 7th Avenue front.

Fig. 5. — Union Station, Washington D. C. — Coach yard and engine facilities. — No scale.

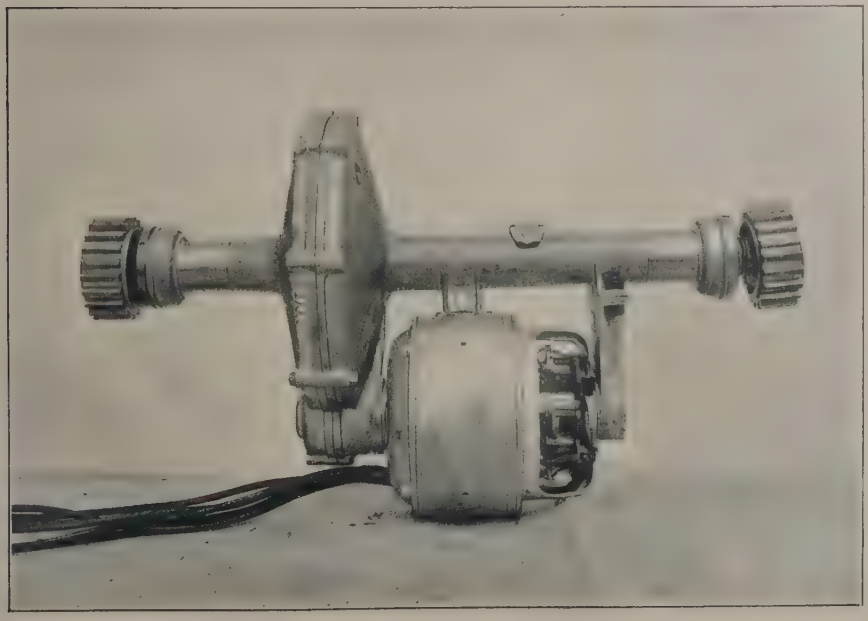

Fig. 7. — Electric baggage truck. — Assembled cam shaft and motor unit.

*

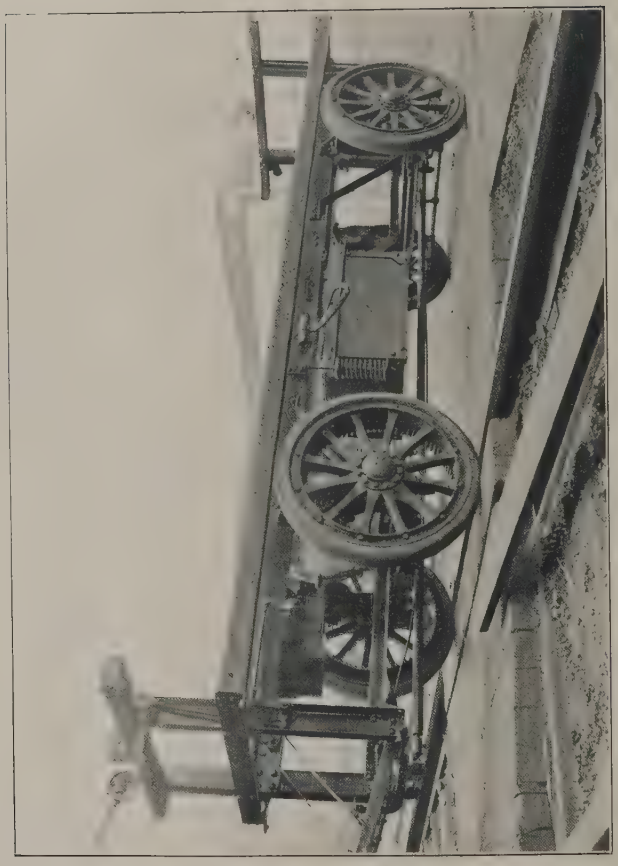

Fig. 8. — Electric baggage truck. — View of the chassis.

From the street level upward, the walls of the structure rise to a height of 60 feet, except in the center, where the roof of the general waiting room reaches a height of 150 feet, and the corner of 8th Avenue and 33rd Street, where there is an elevation of four stories for office purposes. The architectural exterior effect is that of a Doric colonnade, 55 feet high, surmounted by a low attic, raising the general elevation to 60 feet. The exterior construction is of pink Milford granite. The dimensions of the passenger station building are: 774 feet long; 455 feet wide. Dimensions main waiting room: 277 feet long; 105 feet wide; 150 feet high. The dimensions of concourse are: 340 feet long; 210 feet wide.

The character of the station has made it particularly difficult to arrange the various installations, such as ticket offices, baggage rooms, parcel rooms, etc., convenient for all of the general public, inasmuch as the station will be entered in many directions. The effort has been to arrange these installations so as to cause the passengers to cover the least possible distance under the various conditions. A passenger coming by carriage to leave New York, and entering the station by the 31st Street carriage drive, first has his baggage removed to the baggage room, where he is given an exchange coupon. He then leaves his cab and enters the general waiting room, directly adjacent to the ticket offices, where he can proceed to the baggage room checking counter on the central axis of the building, checking his baggage on his exchange coupon; thence he may, if he desires, go to the parcel room, and thence into the various sub-waiting rooms or directly to the concourse, without in any material way retracing his steps. The interior arrangement provides for the handling of baggage between the train platforms and the baggage room in automobile trucks; lifts are provided for all the platforms at both the eastern and western ends of the station, the platforms being connected from above by overhead passages at the waiting room level and by subways below the tracks, and, further, by a continuous driveway 30 feet wide the entire length of the station under 31st Street. As previously described in this report, three general classes of traffic will be handled in this station. A sub-division of the Long Island suburban traffic is made possible by arranging for shuttle trains at the north end of the station. Wide platforms, independent ticket offices, and special entrances and exits directly from and to the street and to adjacent subways in both 7th and 8th Avenues (when constructed) are provided. This feature of the station permits the rapid handling of large crowds on race days. By means of a skilful arrangement of street exits, entrances, interior stairways, landings, etc., a very thorough separation is made of incoming from outgoing passengers, the separation beginning at the passenger platforms and ending practically at the building line. This object has received much study and has been very successfully attained.

A very complete signalling and interlocking system for the terminal yard and tunnels has been adopted. The system is the electro-pneumatic of the Union Switch & Signal Company; four signal cabins will be employed. The double indication or over-lap system of blocking is employed through the tunnels and up to the yard switches. Track circuit route locking is employed for all switches, with automatic release of sections in the rear of train. Track circuit sections are used in place of mechanical detector bars at switches. Illuminated track models are provided in the towers, showing the occupancy of all track sections, these illuminated models being actuated by track circuits.

The station is for both through and stub end operation, but for the majority of movements it may be considered a stub end station. Through trains will be handled by electric locomotives; all Long Island trains by multiple unit motor car service. A great majority

*

of the through main line trains, after discharging their passengers, will proceed through the East River tunnels to Sunny Side Yard, on Long Island, where they will be turned and cleaned; certain of the Pennsylvania locals and short distance expresses will be switched in the yards at the west end of the station and returned without going to the main cleaning yard above referred to. No loop has been employed for turning trains, except as a loop forms the entrance to Sunny Side yards. Shortly after the opening of the station, all cars entering will be of steel.

Area of Terminal Yard (10th Avenue to normal tunnel section east of 7th Avenue)	28 acres.
Length of trackage	16 miles.
Number of standing tracks at station	21.
Length of platforms adjacent to passenger trains	21,500 feet.
Number of passenger platforms	11.
Number of baggage and express lifts	25.
Weight of station building, steel	25,000 tons.
Total excavation required	3,000,000 yards.
Storage capacity of station yard	586 cars.
Maximum capacity of tunnels to and from station in trains per hour	144.

2 single tracks under North River.
4 single tracks under East River.

Union Station, Washington.

The chief architectural line of the building is the Roman Arch, and the entire effect is appropriate to the Capital of the Nation. It is constructed entirely of white granite; 621 feet long, and from 65 feet to 120 feet in height. In the center is a general waiting room 150 feet wide and 220 feet long, modelled after the Baths of Diocletian. The concourse, 150 feet by 750 feet, is divided its entire length by the usual fence, placed 85 feet from the station building walls. A portico runs across the front and sides, affording protection from the weather. Facing the station is a plaza, 500 feet wide by 100 feet long, from which radiate nine avenues and streets.

The ticket offices and baggage departments are in close proximity to the waiting room and concourse. One end of the building is devoted to a special entrance and waiting rooms for the President of the United States and distinguished guests of the Nation. The upper stories of the building are utilized for executive offices.

20 stub tracks are on the concourse level and 8 through tracks are on the basement level leading from the tunnel, with 3 storage tracks along the eastern side for baggage and mail cars. The tracks on the upper level are served by 13 platforms provided with umbrella sheds; the lower tracks are served by 5 platforms. Of the 13 platforms on the upper level, 3 are used for handling baggage, mail, and express matter, exclusively, each platform serving 2 tracks. At the end of these, next to the concourse, are elevators leading to the baggage room in the basement. The passenger platforms are 915 feet long and 20 ft. 7 1/2 in. wide. Nearly the entire basement is used for the handling of baggage and mail matter. The level of this floor is 16 feet below the concourse, and is reached on the

east and west sides of the building by a driveway descent from the plaza level on a 6 per cent grade. Baggage from trains standing on the high level tracks is delivered to the sorting room, either by elevators at the south end, which open directly into the large space under the concourse, or by the elevators at the north end, which open into a runway parallel to 8th Street. North of the station tracks, on the east side, lie the express companies' building, 60 feet by 420 feet. A power plant, 75 feet by 255 feet, and car inspectors' storehouse, 50 feet by 150 feet, are situated almost directly across the yard from the express building. A power tunnel connecting the power house and the station is located next to the west retaining wall. A turn-table, just beyond the power plant, is used in emergencies. All the roundhouses and car storage yards are outside the city limits.

The following railroads enter this station :

Pennsylvania Railroad;
Baltimore & Ohio Railroad;
Washington Southern Railway, and the Richmond, Fredericksburg & Potomac Railroad;
Southern Railway;
Atlantic Coast Line;
Chesapeake & Ohio Railroad;
Seaboard Air Line.

B. — CONCERNING LARGE FREIGHT YARDS.

QUESTION 1. — "*Are the tracks at some of your sorting and shunting yards arranged so as to insure continuity of movement, in one given direction and consequently without any reversal of the cars to be handled, from the time an arriving train is received until a train is made up and ready to depart?*"

Almost all recently built yards groups secure continuity of movement through the various component yards. The older yards were, in many cases, merely collections of sidings, added to from time to time as the business increased. They necessitated tail switching without securing continuity of movement. The usual arrangement consists of a receiving yard, with long tracks to receive trains from the road; thence the cars pass into a classification yard; thence into a departure yard; and thence out on the road.

QUESTION 1-*a*. — "*Are these tracks on a continuous incline, so that the cars can be classified by gravity without requiring a locomotive, or do they consist of successive groups of level tracks commanded by humps on to which the trains are put by locomotives? Are there successive gridirons or specially arranged yards which allow a train to be classified according to destination and on which the making up of local freight trains, preference trains and others*

of limited tonnage can be completed? In case of full tonnage trains, do you use a distinct departure yard in advance of the classification yard? What track arrangements do you use for handling cripple cars and cars to be cut out for any reason?"

The present practice shows an extensive use of the hump between the receiving and classification yards. Locomotives push the trains to be classified over the hump, and they run by gravity to their appropriate tracks, switches at the entrance to the classification yard being worked in the larger yards by air or electricity, and in the smaller yards by hand levers. In a recent compilation, out of a total of 510 classification yards shown, 82 are hump yards. In this compilation, the Baltimore & Ohio Railroad shows 8 hump yards out of a total of 18; the New York Central & Hudson River Railroad shows 3 hump yards out of a total of 9; the Pennsylvania Lines East & West of Pittsburgh show 31 hump yards out of a total of 209; the Chicago, Rock Island & Pacific Railway, the Michigan Central Railroad, the Missouri, Kansas & Texas Railway, and the Wabash Railroad are shown as contemplating hump yards. Intermediate in age between the old collection of sidings and the hump type is the poling yard. Few yards of this type are now being built.

The Northern Pacific Railway replies thus :

This Company has no modern yards designed to handle a complicated traffic. Its new yards are intermediate terminal points, and aside from having separate east and westbound yards on double track divisions, has no special features in this department.

The St. Louis & San Francisco Railroad reports :

We have no switching yards which are arranged to insure continuity of movement in one direction from the time an arriving train is received until the train is made up and ready to depart; neither have we any hump yards. Classifying of cars according to destination is ordinarily done on one or more of the tracks in the same yard which the train enters on arrival. Outgoing trains are ordinarily made up on one or more tracks of the same yard. In some cases, we have one or two tracks which are used practically as a departure yard.

The Buenos Aires Great Southern Railway replies :

Of the class mentioned none exist on this system.

The Philadelphia & Reading Railway is the only road which reports a yard on a continuous incline. That road says :

In the yard at St. Clair a continuous incline is used, and cars are classified by gravity and without the use of a locomotive. In the yard at Rutherford a hump is used between the receiving and classification yards over which it is necessary to push cars to be classified by a locomotive.

Gridiron yards are not used. Usually the work of detailed classification is done

by means of tail switching at the end of the classification yard. This is recognized as very disadvantageous, since it interferes with the movement out of the classification yard. The De Witt Yard, of the New York Central & Hudson River Railroad, shows a westbound reclassification yard alongside and parallel to the westbound advance yard. Eastbound fast freight and way freight sorting yards lie in part between the eastbound classification and eastbound advance yards. Gardenville Yard, of the New York Central & Hudson River Railroad, shows the same general characteristics. The new Northumberland Yard, of the Pennsylvania Railroad, shows a somewhat similar arrangement. In other words, while the old practice is to accomplish the refinements of classification by tail switching, the new yard designs show specially designed yards for this purpose.

Use of distinct departure yard.

The general practice in the case of almost all the large modern yards is to show a distinct departure yard in advance of the classification yard.

Crippled car arrangements.

The usual arrangement for handling crippled cars is to assign a track in the classification yard into which they drop from the hump. Two roads report a cripple yard or cripple spurs having a direct connection from the hump. This arrangement is usually impracticable, since the space between the receiving yard and classification yard is too small to permit of a repair yard. The new Northumberland Yard, of the Pennsylvania Railroad, shows special treatment of this feature. Enola, Altoona, Pitcairn, Conway, Scully & Chicago Yards, of the Pennsylvania System, show varying methods of handling the cripple car problem. Cars are inspected in both the receiving and classification yards. In many instances, classification and departure yards are fitted with air plants to test air brakes, charge the trains, etc.

QUESTION 1-*a*. — *Do you use separate yards in classifying local freight, preference freight and through regular freight? That is, do you feed all the above classes of cars over one hump into one classification yard, or do you separate the above classes at the entrance to your yard and handle the three classes in separate yards and over separate humps?*

The general practice in yards of recent design is to feed all the various classes of loaded cars into one receiving yard and push them over the same hump into one classification yard. As a rule, the various classes of freight are not separated at the entrance to the yard group.

The following replies are characteristic :

Chicago, Burlington & Quincy Railroad.

All cars in one direction go over the same hump.

*

Delaware & Hudson Company.

Feed all over one hump into one classification yard.

New York Central & Hudson River Railroad.

Separate pockets of the classifying yard are used, or a small additional reclassifying yard.

Pennsylvania Railroad.

All trains except preference trains are fed over humps in the order of arrival. Preference trains handled on flat track. (At Pitcairn Yard the preference trains are fed over the humps.)

Pennsylvania Railroad Lines West.

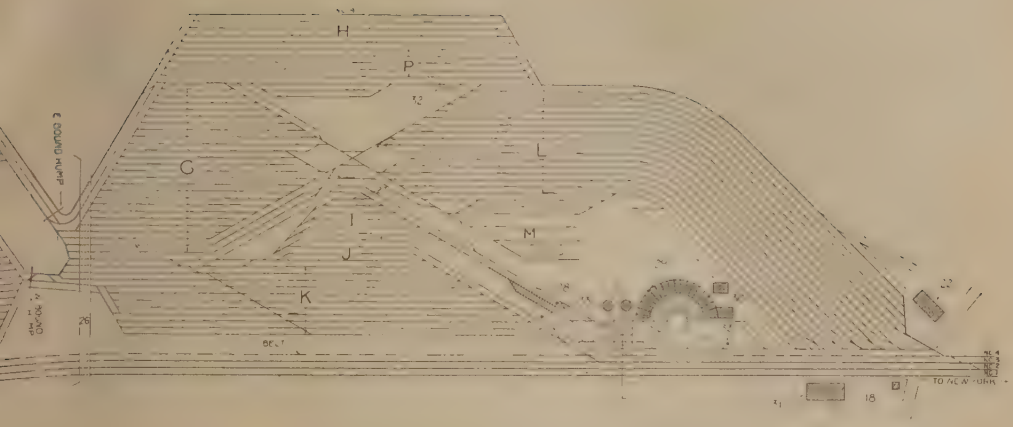
Generally they all over go one hump into one classification yard. In very large yards sometimes more than one hump is used, in which case some such division of work as suggested in the question may be adopted.

Grand Trunk Railway.

No.

Baltimore & Ohio Railroad.

Separate yards are not provided for classifying local freight, preference freight, and through freight; but all classes of cars are fed over one hump into one classification yard.



on River Railroad. — No scale.

. . . = Coaling station.	19. . . . . = Inspector.	27. . . . . = Empty coal car tracks.

Chicago, Rock Island & Pacific Railway.

The Rock Island have never built any hump yards, but our preference would be not to use separate humps for classifying local freight and through freight, but only use one hump for all kinds, and if the business grows so as to require more than one hump, build another hump.

Northern Pacific Railway.

No.

Questions 1-*b* and 1-*c*. — *What system is adopted for stopping and again starting the cars in the cases mentioned above (hand brakes, sprags, skids, etc.)?*

Are all the cars which are classified at yards with continuous inclines fitted with hand brakes? How is the work carried out when this is not the case?

What arrangements are adopted for stopping run-aways (chain-drags, safety sidings, sand tracks, etc.)?

Hand brakes, which are provided on all cars, are depended upon to stop the cars. On certain roads the speed is limited by rule to 2 miles per hour. In the case of hump yards, men ride the cars down the humps into the classification yards and

apply the brakes as required. Effort is made in designing the grades of the hump and classification yards to so ligten the grades that the cars will stop of themselves near the end of the classification yard. The cars are started again by locomotives.

The Chicago, Burlington & Quincy Railroad replies :

All cars with bad brakes are coupled with cars with good brakes when practicable. At times cars with bad brakes are handled with a switch engine used to bring the car riders back from the foot of the incline.

Erie Railroad.

In the case of a defective brake the car is not cut off, but is placed with a locomotive.

Pennsylvania Railroad Lines West.

It is the duty of the inspectors to see that all brakes are in good order before the cars are sent over the hump.

Baltimore & Ohio Railroad.

In case of failure of hand brakes, the grade at the other end of the yard is such that the cars will stop before reaching the ladder track ; or if the track is partly filled with cars the contact will be insufficient to do anz appreciable damage.

In a few yards derailing switches are found. Skids, chain-drags, rail shoes, and sand tracks are used in exceptional cases.

Question 2. — *Have you adopted any arrangement of tracks making it possible to eliminate any interruption of the classification and making up operations owing to the arrival and departure of trains ? What is your arrangement in regard to position of roundhouse and car repair shop to allow 1° and 2° ?*

All recent designs are intended to eliminate interruption of classification due to arrival and departure of trains or to the various currents of movement, such as road engines leaving and moving toward trains, shifting engines, movement of crippled cars, distinct classification of local freight trains, etc. The results obtained are satisfactory, and the more successful yards suffer little interruption under normal conditions.

It is generally recognized that the position of the roundhouse should be near the center of the yard group, that is, if the east and westbound yard systems lie directly opposite each other, then the roundhouse should be in the middle space between the two humps leading into the cassification yards. Local circumstances, topography, preponderance in direction of traffic, necessary distribution of yard buildings, etc. affect this situation. Few yards actually show the roundhouse in the

center. In certain yards, it is necessary to provide a transfer house for package freight, ice houses, storage spaces, etc. All of these considerations enter to affect the position of the roundhouse and car repair shop. In general, endeavour is made to so place the roundhouse as to involve about equal travel for the road engines of the entering roads in reaching it and leaving it, while causing the least interference with other movements. No generalization can be made of the various replies as to the actual position of car repairs yards. The individual conditions are too unlike. On this question the Delaware & Hudson Company says :

Leads to roundhouse and repair tracks separate and distinct from the yards.

The Erie Railroad says :

Generally the roundhouse and car repair shop to allow 1° and 2° are located midway between the east and westbound freight yards.

The Pennsylvania Railroad Lines West say :

The roundhouse should be located near the center of the cluster, or general yard.

The Pennsylvania Railroad says :

Tracks are so arranged that there is no interference due to arrival and departure of trains. Roundhouse and car repair shops should be located between the east and west or north and south yards.

The Chicago, Rock Island & Pacific Railway says :

We aim to arrange the tracks so that there is no interruption to the switching arrangements during the arrival and departure of trains. Sometimes we have been obliged to depart from this but have always provided a place for switching engines with their trains to stand while trains are arriving or departing.

Question 3. — *What importance do you attach to the realization of the different preceding conditions (continuity and uniform direction of movement, elimination of all interruption to shifting operations) ?*

Does the advantage obtained by this realization justify, to the same extent in each case, the large size to be given to the yards and the resulting expense ?

The concensus of opinions of all roads is that uninterrupted classification is of the greatest importance, and that expenditures to obtain this have been justified by results.

It is believed that by the aid of a hump cars can be handled more quickly and at lesst cost than with any other form of yard. The success of the operation may be judged from the following results shown in a representative yard, where mineral

traffic is handled in large volume, confining the figures given to the eastbound side, except where specified :

Maximum number of trains entering the yard in one hour is 7, with an average number of 50 cars per train.

Average number of trains entering the receiving yard in 24 hours is 33.

Average train pushed over the hump is 68 cars, 3,800 tons.

One pusher engine is used in handling some of the trains, but with the majority of trains it is necessary to assist the pusher engine with a pole which works alongside the train to be shifted. Two engines are used in extra cold weather only.

Cars to be weighed are uncoupled. The scales are not located on the hump. The amount of weighing is small, and does not interfere to any great extent with the work.

The classifying capacity of the hump as determined by continuous operation is as follows :

	Eastbound.	Westbound.
One hour.	81 cuts.	108 cuts.
Five hours	291 —	389 —
Ten hours	580 — 1,318 cars.	688 — 1,396 cars.
One day (24 hours)	900 — 2,151 —	1,205 — 2,488 —

The hump is in actual operation 15 $^1/_2$ hours out of each 24.

There are 15 car riders employed.

The switches are operated by air. One man is assigned to this work at each hump.

The cost per car for yard handling (from the time the road engine is cut off on the receiving track until the road engine is coupled to the train on departure track) is $0·10.

The cost per car, averaged from the operations of 22 representative yards, is $0·13. The figures vary from $0·05 per car for the Winnipeg Yard, of the Canadian Pacific Railway, to $0·32 per car for the Potomac Yard, of the Washington Southern Railway.

Three railroads state that the advantage obtained from the use of the large yards justifies the expense in about the same degree in all cases. The general feeling expressed by the roads, however, is that the advantages are not alike in all cases; that the matter depends upon the volume of traffic and on local conditions. The St. Louis & San Francisco Railroad says :

We feel that the expense incurred for the elimination of all interruption is ordinary fully warranted.

Question 4. — *Please enclose in your answer plans of the yard or yards best satisfying the two conditions 1° and 2° above. Please also state what area is occupied by these yards and what the total length of track is, and how many cars are handled every twenty-four hours ; each car arriving at the yard to be counted as one unit only.*

A list of plans of yards appended to this report follows, together with available

data as to area occupied, total lenght of track (thesefeatures in part scaled), and number of cars handled in 24 hours.

Some of these plans (figures 9 to 15), have been reproduced for publication. Where distortion of the plans has been necessitaded to allow reduction to a size to permit of photographic reproduction, the words "no scale" have been marked.

A synopsis of a study for the New York Central & Hudson River Railroad Yard at Gardenville, New York, for the Buffalo territory, is given. It shows a most consistent working out of the various features and, in general, very elaborate arrangements.

The westbound yards are shown in the following order:

Receiving yard of 20 tracks of 100 cars each;

Three car repair yards which can be reached from either the receiving yard or classification yard;

Hump leads from receiving yard into westbound classification yard, which is divided as follows:

Interchange with minor connections;
Buffalo deliveries and transfers;
Interchange with principal connections;
Symbol time freight;
Symbol drop trains;
New York Chicago & St. Louis Railroad.

Total, 3,195 cars.

Two grouping yards;

Car transfer yard;

Hold yard for cripples;

Main assembly tracks for westbound Buffalo local movement;

Westbound reclassificatien yard, preceded by a hump;

Westbound advance yard;

Westbound symbol advance yard.

The eastbound arrangement is on similar lines.

Two New York Central enginehouses are located in about a central position with respect to the westbound classification yard and eastbound advance yard.

Separate car repair shops for eastbound and westbound cars are located parallel to the general axis of the yard and in the immediate neighbourhood of the respective yards.

GARDENVILLE, NEW YORK YARD, NEW YORK CENTRAL & HUDSON RIVER RAILROAD.

Car capacity of body tracks of individual yards.

C. — CONCERNING LARGE FREIGHT STATIONS.

Question 5. — *Please describe : 1) The appliances which you are now using for handling freight.*

Two types of trucks are in common use : First, a two wheel wooden frame truck. It is of good design and fairly well balanced, and is used at both freight and transfer houses. Plain bearings are now used, but this type of truck is now being experimented with in all steel in three designs, as follows :

One half barrel design, estimated weight.	150 lb.
— — — — —	155 lb.
One full — — — —	156 lb.

The all steel truck is half barrel design. Second : The four wheel truck known as the Reynolds truck is used at many stations. This truck weighs 370 pounds.

The Pennsylvania Railroad is considering a truck similar to the Reynolds truck, which weighs 380 pounds, and is much more substantially built. The rear wheels are located some distance from the end of the truck, and they carry about two-thirds of the load. They have roller bearings. The front wheels or castors are mounted on swivel ball bearings, and the truck is easily turned by one man in any one direction, on its bearings or in its own length, with a load of 2,500 pounds. The cost of this truck is estimated at about $20·50.

For the handling of heavy freight, such as pianos, safes, etc., a six wheel truck is used. The two center wheels are of a slightly larger diameter than the others and are located inside of the frame. This permits the truck to be turned in a very small circle.

Special trucks are in use at some of the larger stations where the character of the freight handled is of such a nature as to demand special devices, such as pipe and plate glass handling trucks. They are rather exceptional, however.

Fixed jib cranes and overhead cranes : The overhead cranes usually span one or more tracks and a driveway. In some cases the bridge is fixed, in others the bridge moves on an elevated track, and in still others the bridge is supported by towers which move on surface tracks. In many instances, the travelling electric cranes are of 30 to 40 ton capacity, with auxiliary hoists of 5 to 7 ½ tons for lighter weights.

In storage warehouses horizontal conveyors (roller, chain, platform) are coming into use, as well as overhead travelling cranes. Likewise, in storage warehouses the carrier systems are proving efficient, especially in long pier houses, where the movements are longitudinal and free from complications. The telferage system, consisting of steel runways on which are operated electric hoists and travellers, is successfully and economically operated in such cases. Vertical elevators, hydraulic and electric, are commonly used. Speed about 20 feet per minute.

The Buenos Aires Great Southern Railway says :

No special devices are in use, except at one or two stations at which there are ordinary traversers and capstans for moving wagons.

Question 3-II. — "*Any experimental devices which you may be trying for handling carload and less than carload freight ; and describe the results obtained as to efficiency and economy of such devices.*"

Plans have been drawn by a number of railroads for improving the methods of handling freight, and, more especially, package freight in city stations. Different arrangements and combinations of trolley systems, industrial railroads, telfer,

machines, moving platforms, truck conveyors, etc., have been considered, but little has been actually accomplished. In a particular instance of a two-level city receiving and forwarding station, the manufacturers were able to produce a machine which would move a number of trucks along a floor and up an inclined plane to a second story and discharge the trucks automatically, but the project as a whole has not been successfully accomplished in the case of less than carload freight. This freight varies greatly in weight and bulk, and it cannot be assured that part of the lading will not fall from the truk and stop or wreck the machine; the automatic discharge

of the trucks at a high level requires men to be on hand to relieve the machines and move the trucks promptly to outbound cars; the freight is received from teams in great volume from about 2·00 to 6·00 p. m. In the morning hours little freight is received, but the machine may have to be run the greater part of the day, and the trucking force must be hired for all day. Considering all the complications and costs, it was decided to be better in this particular case to continue to use the old-fashioned hand truck and vertical elevator. This experience may be regarded as typical.

The Baltimore & Ohio Railroad replies :

No experimental devices are being used :

a) Freight is handled exclusively by trucks, except at Locust Point, Baltimore, where we have the telferage electric trolley system, with overhead tracks and hooks by which the freight can be transmitted from one part of the freight house to another;

b) Freight is handled by trucks and elevators, except at grain warehouses, where it is handled by endless belts. Gantry cranes are provided at all freight delivery yards for handling heavy materials.

(Locust Point, however, is not a general receiving and forwarding freight station, but a pier, and the movement is simple.)

The Chicago, Rock Island & Pacific Railway replies :

No experimental device being tried, although we have been studying a method of handling cotton to and from platforms by machinery :

a) We are using platforms with stub end tracks so as to readily unload automobiles either from side doors or end doors; always provide for a crane so as to handle bulk freight to and from wagons; also provide outside platforms so that large and bulky freight can be unloaded onto them and taken away by teams without passing through the freight stations.

b) We do not have more than one floor to our freight houses, except for offices.

The Northern Pacific Railway replies :

No such conditions.

Again, to operate the trolley system requires additional height between floors, in order that the truck or platform when in motion will not be in danger of striking employees ; this adds seriously to the building cost.

The Pennsylvania Railroad has a vertical barrel and package conveyor at its new Duquesne Freight Station, Pittsburgh, but in experience it is found that " it is only practicable to convey barrels and kegs; it is not suitable for packages at all; the maximum capacity we have been able to develop is 300 barrels of sugar 360 pounds each in 70 minutes with 5 men. Our elevators perform the same service in 57 minutes with 4 men. A machine of this type is not economical in a warehouse like ours where such a variety of merchandise is handled; moreover, it is frequently out of gear and cannot be set in motion and shut off instantaneously like an elevator ".

The New York Central & Hudson River Railroad says under II :

None being used experimentally.

a) No mechanical devices, except on open docks, where " fast plants " are used.

b) Elevators and barrel hoists are the only devices used.

QUESTION 6. — *What improvements or developments in the design and general arrangement of large freight stations are being made as the result of the necessity of elevating tracks in large cities or for other reasons?*

The necessity for elevating tracks in cities has brought about freight stations where the track level is on the second floor. This has brought to bear on the freight station problem much study and analysis of conditions tending toward a closer view of design and of operation. With this change has come also the development of storage houses overhead. It has been found advantageous for railroads, in the case of terminal warehouses, to add three or more overhead stories, so as to afford merchants and commission men an opportunity to have their goods stored on arrival and shipped on order; the outbound shipments being loaded into cars and moved out directly from the freight house. In this way cartage is saved, which in large cities amounts to as much as $0·80 per ton. As a result of the necessity for larger buildings, much larger sums in the way of investment are involved. Further, the enormous increase in the volume of freight handled in cities, which grows in rough proportion to the increase in population, has contributed to the same result as the necessity for providing storage facilities. Space and property are more valuable and every square foot must be utilized. Committees are appointed when a large freight station is to be designed, whose duty it is to analyze all the conditions and recommend a station constructed on the best lines for the purpose in view. This brings into the problem the Freight Agent, who will operate the station; the Engineer, who will construct it; the Train Master, who will be concerned in the moving in and out of cars; the Superintendent of the storage warehouse, who is concerned in the speed and economy in moving the freight from the freight house level to the various floors, the storage and safe preservation on those floors, and the subsequent lowering of this freight to the freight house floor for loading into cars and drays. These conditions have led to a study of economical widths, lengths, heights, dimensions of station driveways, paving, track lay-out, position and construction of elevators, improved office arrangements, including mess room, toilet rooms, etc. for the Agent's clerical force (in large stations this runs up to 60 to 90 men), and the cashier's office, where the public transacts its business. The freight houses have been divided into fire proof compartments by means of interior automatically closing doors; overhead automatic sprinkling systems for the extinction of fires have been provided. It has led to a study of door construction, including junction doors; to better ventilation, drainage, and to improved trucking floors. The improved type of floor consists of maple wood, 8 inches by $\frac{7}{8}$ inch, tongued and grooved, laid diagonally on creosoted yellow pine; this rests on sleepers set in sand, tamped clay, or ballast.

*

Close analysis has been made as to the use of improved machinery for handling carload and less than carload freight. As already stated, however, no very definite results have been reached. A very notable tendency is observable in Chicago, where many of the freight stations are connected with a freight tunnel system which runs under the entire business portion of the city, so that the freight on arriving at a railroad station is loaded into a small car of about 2 tons capacity. This is lowered by an elevator to the tunnel level, and is there moved by electric motors to the basement of the consignee. In a similar way, outbound shipments from the basement of the consignor are loaded in these cars and moved through the subways, elevated to the freight floor of the particular railroad and loaded into outbound cars. The natural development of this change will have a large effect on the design of stations as they are remodelled in the future. A similar system is under contemplation for a portion of the business district of New York City.

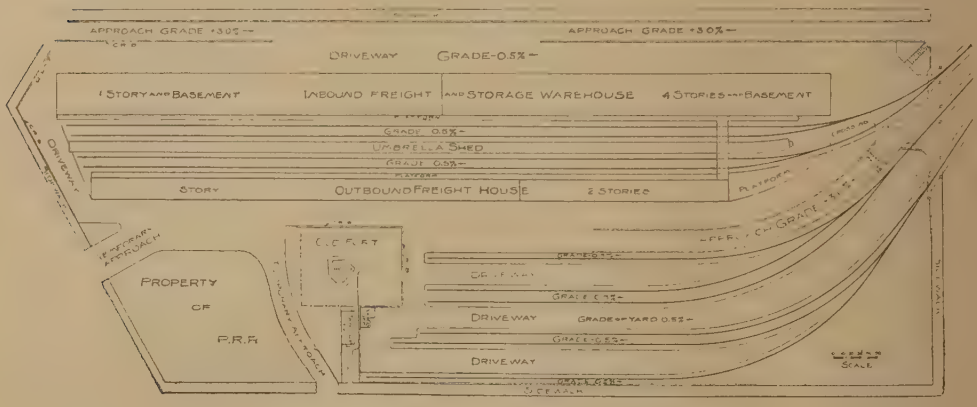

Fig. 16. — Duquesne freight yard, Pennsylvania Railroad.

The old type of freight station consisted of a receiving and forwarding platform, with two or more long tracks, all under one roof. The new type consist of separate inbound and outbound houses, each under a separate roof, with a number of stories for storage purposes over the inbound side. Between these two houses are placed three, four, or more tracks. Between the tracks are placed a number of platforms covered by sheds of improved design, for trucking between the cars.

REPORT N° 2

(Russia, Austria, Hungary, Turkey, Rumania, Bulgaria and Servia)

By A. KAIN (1),

ENGINEER,

INSPECTOR OF THE HUNGARIAN STATE RAILWAY.

We think it advisable, before dealing with the separate questions and the answers received from the different railway administrations, to give a short account of the development of the railway system and of the traffic in the countries with which our report has to deal.

This short account is intended to elucidate the causes which led to the present more or less satisfactory state of development of the large passenger and goods stations in those countries, and the local conditions and external circumstances, which had a bad influence on the design and construction of the large stations, and finally the opinions and principles adopted by the different railway administrations when designing and constructing large stations in the immediate past.

The chief railway lines, both in Austria and in Hungary, were originally built by a number of separate independent railway companies, and the lines built were more or less competing lines according to their geographical position. The same statement also substantially applies to the other countries with which our report deals.

The passenger and goods stations of the

---

(1) Mr. Kain died since his report was sent in.

*

large towns were in most cases combined into one station, in accordance with the needs of the then-existing traffic; but the stations of the different companies were built in different parts of the town. Not only were these separate stations not connected with each other, but the question of facilitating the possibility of making such connections at a future date, should they become necessary, was not even considered.

In this first period of railway development, attention was nearly everywhere paid only to the local importance of the lines, or at most to their importance as regards the country itself.

No provision was made for any connections between the stations at large towns and at traffic centres, made necessary for operating through and international traffic, and thus the larger stations only formed termini of the line concerned.

But as regards the need of a proper through connection of the separate stations in a large town, conditions have now become very much altered, and so have consequently opinions on this point.

Most of the main lines which formerly belonged to companies have in most countries, for instance in Austria, Hungary, Rumania and Servia, become the property of the State; and the lines which are not yet the actual property of the State nearly all fall within the sphere of its influence. Consequently, the need of connecting up the different railway lines, which formed in many cases disjointed sections, became more and more apparent.

Such connections also became indispensable in consequence of the great and unexpected development of the traffic year by year, and in particular that of the through international traffic. The original conception of the nature of railway traffic has accordingly become modified; the frontier of a country is no longer looked upon as a terminal point of the railway but as a transit point, and the terminus proper of the railway is only reached at the seashore, where other means carry the traffic further.

This continual development of the home and of the international railway traffic has made the defects which result from the original design and construction of the large stations very apparent and in some cases even unendurable, particularly those which result from a want of connection between the different stations in one and the same large town.

This makes itself specially apparent in those countries in which the traffic is not uniformly distributed over the whole year, but is chiefly seasonal in its character; it hinders the development of the traffic and consequently also the economical development of the whole country. In addition, these obstacles to the traffic increase the working expenses of the railways and also reduce their capacity and earning power.

But even after these defects and the causes of the evil had been recognized, the work of eliminating them could only unfortunately proceed at a slow rate. There were and still are many more important and urgent requirements in connexion with railways, both from the commercial and industrial points of view, than the eliminating of these defects.

In the first place, there was the construction of new railways, in order to complete the existing railway system and to open up new districts and new sources of natural wealth, and to make as far as pos-

sible all parts of the country equally accessible to the blessings of civilization.

In the second place there was the need, quite as apparent, of providing for the increasing traffic on the existing lines, by enlarging the smaller and the medium-size stations, and by duplicating the tracks.

Only after this work had been more or less completed, was it possible for any of the countries our report deals with to proceed with the extensions of its passenger stations, and to reconstruct them in accordance with modern developments, and also to reconstruct its goods yards and suit them to the growing goods traffic, in order to reduce the working expenses.

As all this work involved a very large outlay, most of the countries could in most cases not proceed beyond the working out of the different schemes, while the carrying out of these schemes will take place in the immediate future. Such is the general state of the question in Russia, Austria and Hungary.

The other countries to which our report applies have not even arrived at this stage, as their whole energy for some time to come will have to be devoted to the construction of the main lines of their railway system.

Passenger and goods traffic, as already stated, has increased during recent decades, and particularly so in Austria and in Hungary.

In Austria, during the last ten years, passenger traffic has increased 50 per cent and good traffic 40 per cent; in Hungary the figures are 75 and 77 per cent respectively.

The railways and their organizations were consequently only able to deal with the growing traffic with safety by making the greatest efforts and by adopting many special measures, often involving much trouble. Among such measures we may mention the increase in the axle-loads of the vehicles and the increase in the speed and the number of the trains; and in order to make this possible, the track was strengthened, the number of passing places was increased, and the existing smaller and medium-sized stations were enlarged.

All this work formed a heavy tax on the resources of the railway administrations.

Particular attention was also devoted to the alteration of the large railway stations at industrial and commercial centres. The general principles on which these alterations were based will be dealt with later on in connection with the separate questions. In these questions, we deal with the passenger stations and the goods stations separately, and we will at once enunciate the principle, already now generally recognized as correct, that the railway traffic at large towns can only be managed quickly and economically, to meet the justifiable demands of the travelling public and of the public interested in the goods traffic, if the passenger traffic and the goods traffic are kept wholly separate. On the other hand, the mails and the quick-freight service are in close connection with the passenger service, as in the countries this report deals with nearly the whole of this traffic is still operated conjointly with the passenger traffic.

It is desirable in the interests of the public, that the large passenger stations should be placed as nearly as possible at the centre of the population according to its distribution.

If the town is a very large one, it is pro-

bably best to have several passenger stations in the different parts of the towns, all in communication with each other and serving for all traffic relations, so that the whole population may be enabled to reach a station with as nearly equal ease as possible.

If there is one central station for the whole town, which hardly would suffice for the traffic in a larger town, it is necessary to have special sorting stations, for sorting and marshalling the passenger trains, as near as possible to the central station, so as to reduce as much as possible the distance the trains requiring sorting have to run.

Such a main or central station will in most cases be in the form of a terminus, and will be supplied, with a view to future requirements, with a large number of halls and platform sidings.

The special sorting stations mentioned, with their extensive sidings and locomotive sheds, are indispensable for sorting and marshalling passenger-train stock, for storing any carriages which have to be added to through trains and any carriages not required at the time, and for changing the locomotives. It is consequently also desirable in the interests of quicker operation that these sorting stations should be as near to the passenger stations as possible.

It is a great advantage if these sorting stations can be placed between the main lines, in order that trains coming from the passenger station to the sorting station, or trains leaving the sorting station and going to the platform sidings, may not have to cross the main lines.

This principle should not be departed from except if the crossing of the main lines at rail-level can be wholly avoided by means of overbridges and underbridges.

If in a large town there are to be several passenger stations in through connection with each other, then a special auxiliary station should be installed at each of two opposite points on the boundary of the town. These auxiliary stations are then the terminal stations of the trains and are to be used as the departure and arrival stations for the adjoining outer parts of the town. The sorting stations mentioned above must in this case be built in connection with the auxiliary stations.

The installations for dealing with the mails and the quick-freight traffic are also best placed at these auxiliary stations, at least in those countries where (as in the case of the countries with which this report deals) the mails and the quick-freight are conveyed by the passenger trains, as the mail and quick-freight matter can in this way be brought conveniently to the passenger trains.

The through lines in the town, connecting the passenger stations and the auxiliary stations, should be either underground or elevated railways, in order not to interfere with the street traffic of the town; and for the same reason, the sidings of the passenger stations should also be above or below street level.

The goods stations, which should be quite separate from the passenger stations, should as far as possible be accessible from the town. But just as in the case of the auxiliary stations and the sorting stations, these goods stations must be located outside the city limits proper, both on account of their large extent and the consequent large expenditure on land, and

because they would interfere with the development of the city.

But the further the goods station from the town, the greater the cost of carriage to and from the station; there is consequently a justifiable tendency to place the goods station as near as possible to the more densely-populated parts of the town, and near to the industrial and commercial districts, to suit the existing conditions.

The sorting and shunting yards must however in all cases be placed outside the populated districts, where land is cheaper and no consideration has to be paid to the surroundings and where consequently in designing the installations attention can exclusively be paid to the proper quick and economic operation of the traffic.

It is self-evident that the sorting and shunting yards should have a short and as convenient a connection with the goods stations as possible, and if necessary also with the passenger stations.

In large towns, where there are several goods stations, it is advisable to have a central sorting and shunting yard as the freight carried on the different railway lines usually includes a good deal of through freight, which if there is more than one sorting and shunting yard would in most cases have to be taken from one to the other. In addition many consignments are handed in at the different goods stations which would not be added to the corresponding train at the adjoining sorting and shunting yard but at one further off. This would result in much unnecessary work and additional expense, and the junction lines would tend to become congested; all this can be avoided by having one central sorting and shunting yard only.

The above-mentioned separation of the passenger stations and of the installations for dealing with goods has however only its full effect in cases where there are already separate lines for carrying the passenger and the goods trains. This can however only be the case where there is much traffic. It is however absolutely necessary that the tracks should be separated in this way at least as far as the next stations.

At large towns where the coal required for the use of the inhabitants is stored, in the absence of other installations, at the stations, it is very advisable to construct special coal yards, of suitable design.

At many of the large stations in the countries our report deals with, the passenger, goods and sorting stations were rebuilt during the last ten years, the principles enunciated above being adopted either wholly or partially. At other stations this transformation has been begun or is going to be begun, in other cases the plans have been worked out.

The questions arising in this connexion will be considered separately in the following sections of this report.

A. — Large passenger stations.

Question 1. — *Have you adopted special arrangements in order to increase the working capacity of your stations and to ensure the safety of the shunting operations? More especially : a) Are the tracks for main-line trains grouped together in a set separate from the set of tracks used for suburban trains?*

A busy short-distance traffic can, as a rule, only exist in the case of very large

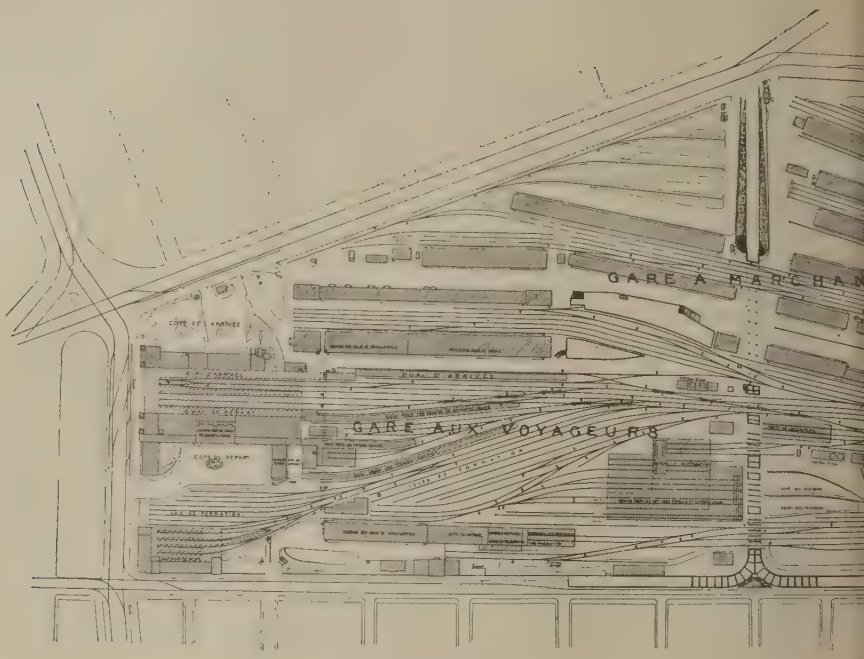

Fig. 1

Explanation of French terms : Côté de l'arrivée = Arrival side. — Quai d'arrivée = Arrival platform. — Quai

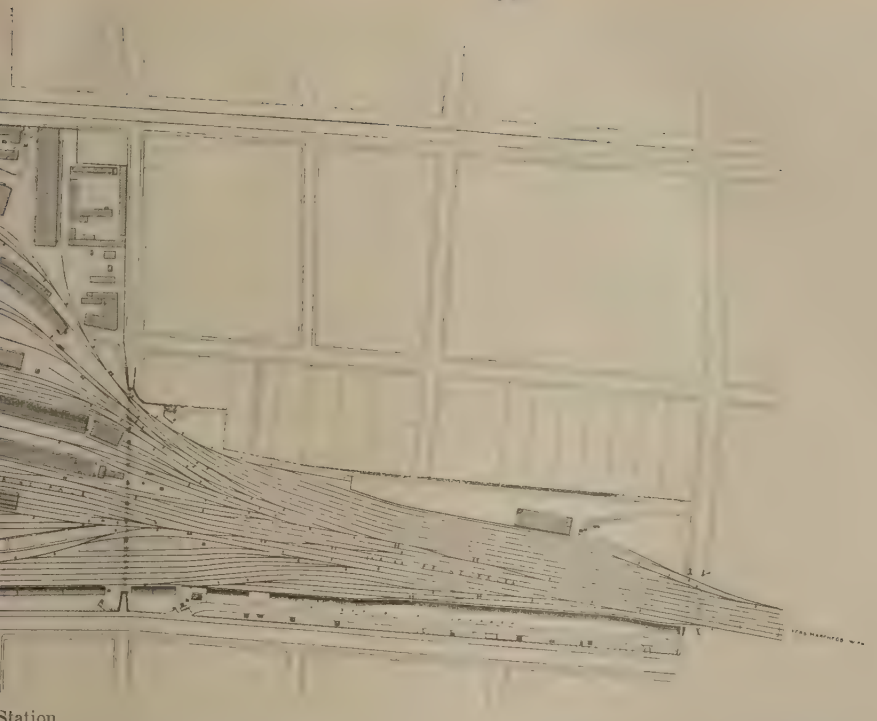
towns. In the countries with which our report deals the suburban traffic of these towns is only in part operated on the main lines and only in so far as the lines to the passenger stations in the large towns also carry a large number of local trains. This is for instance the case in Austria on the lines to Vienna, particularly on the Vienna-Mürzzuschlag line; in Hungary on the Budapest-Párkánynána, the Budapest-Szolnok, the Budapest-Bicske and other lines. At present there are two chief passenger stations at Budapest, where the daily traffic amounts to about 300 passenger trains; 130 of these are local and suburban trains. The local trains of course stop at each station and even at each halt.

But there are also shorter railway lines which go to the large towns, which carry no long-distance traffic; but the trains on them as a rule also use the passenger stations of the railroads. Such are for instance in Hungary the Budapest-Esztergomer and the Budapest-Lajosmizse-Kecskeméter lines, which all go to the Budapest West station.

Finally, there are also at these large towns shorter railway lines which are



Station.

latform. — Côté du départ = Departure side. — Voies de formation = Marshalling siding. — Bâtiment de poste = Platform for local trains. — Gare aux voyageurs = Passenger station. — Gare aux marchandises = Goods rincipales = Main lines. — Château d'eau = Water-tower. — Vers Marchegg-Wien = To Marchegg-Vienna. —

quite independent of the main lines, which are also exclusively used for short-distance traffic, but do not touch the passenger stations of the main lines, and have their own local stations as termini. To this class belong for instance the local lines Budapest-Haraszti, Budapest-Czinkota, Budapest-Szentendre and Budapest-Nagytétény, most of which have no connection whatever with the tracks of the passenger stations of the main railroads.

To a certain extent the Vienna Stadtbahn was also built for this purpose, although its chief object was to carry city traffic proper.

Special sets of tracks reserved for short-distance traffic are only to be found in very few stations in the countries with which our report deals; for instance in Triest and Salzburg.

The explanation for this fact is that at the time when these passenger stations, such as all Vienna and Budapest passenger stations and others, were built, the short-distance traffic was still in a very elementary condition and it was consequently unnecessary to devote special tracks to it.

Later on however, when short-distance

traffic in most of the large towns had become enormously developed, and it would have been desirable to have such installations, these could only have been constructed with much difficulty, owing to want of room and the great expense involved in extending any station which is inside a large town.

Any such extension of a large station is made particularly difficult by the circumstance that such a station forms a natural centre of attraction and soon becomes surrounded by new hotels, banks and industrial establishments.

Hence attemps were made to deal with the short-distance traffic, at least for a time, by means which did not involve building operations, so that the short-distance and the long-distance traffic could still be operated, at least for the time being, on one and the same set of tracks.

Such an expedient for instance consists in running the local trains at other hours than the long-distance trains, so that both can use the same sets of tracks; the latter trains chiefly use the large stations between 5 and 10 a. m., 12 and 3 p. m., and 6 and 11 p. m. This division we find at the large stations of most countries.

Another expedient we find for instance on the Vienna-Triest line of the Austrian Southern Railway; the long-distance trains and the Vienna local trains arrive and depart on the same set of tracks at the Vienna South station. On Sundays and holidays, when the ordinary number of local trains no longer suffices for dealing with the enormous local traffic, some of the long-distance trains are taken from Vienna to Vienna Neustadt over the single-track line Vienna Pottendorf-Vienna Neustadt, in order to leave the two tracks of the main line wholly free for additional local trains.

Most of the passenger stations at Vienna already belong to the State (State, North, North West, West, and Franz-Josef stations); these terminal stations have no connection. In this case it is possible, and intended, either to replace these terminal stations by new stations properly connected together, or to reconstruct the stations and make proper connections between them. If this plan is carried out, it is certain that special sets of tracks for local trains will be provided in the case of those lines which carry a heavy local traffic.

It becomes still easier to operate the traffic if in addition to the tracks at the stations, special tracks are also reserved on the open line for the local traffic and especially for the long-distance traffic. In most cases, it will however hardly be possible to do so and one will be limited to having separate tracks for the short-distance and the long-distance traffic at the stations.

The passenger stations at Budapest, the West and East stations, were built at different periods, by different owners, and had no connexion with each other. Today these chief stations are the property of the State and both are also used by through international trains, which carry the passenger traffic between the East and the West.

At both the West station (fig. 1) and at the East station (fig. 2), in Budapest, the station buildings and the tracks are at present being altered, so that separate sets of tracks will soon be available for the long-distance traffic and for the short-distance traffic. On the arrival side of the former station, local conditions will how-

ever make this separation impossible.

The alterations at these two stations, which are nearly completed, had however only the object of reducing the difficulties in connexion with the passenger traffic in the capital city of Hungary, at least until the general reconstruction of Budapest stations can be carried out; the plans for this have been prepared and part of the scheme has already been begun.

The two stations are comparatively small, and have four and five tracks respectively; they accommodate nearly 300 trains per day. The total number of passengers at the two stations amounted in 1908 to about 19 millions, and the average annual increase varies between 1·5 and 2 millions.

The scheme for reconstructing the passenger stations includes the construction of an auxiliary station in the northern suburbs and of another in the southern suburbs, at suitable spots, each connected with a sorting station with the necessary installations for operating passenger traffic.

In addition to these auxiliary stations and the sorting stations connected with them, it is proposed to build inside the town two other chief passenger stations (through stations) in suitable positions and at a suitable distance from each other. All these stations are connected in such a way that trains for any destination can be boarded from either station and also can arrive there from any destination.

The tracks used for the long-distance trains will also be used for some of the short-distance trains except as regards certain local and short-distance trains for which two special tracks will be provided.

In this way both the local traffic and the short-distance traffic will be partly separated from the long-distance traffic, but they will still remain in contact with each other. The diagram (fig. 3) shows how it is proposed to operate the passenger traffic.

Another circumstance worth mentioning is that the tracks exclusively used for short-distance traffic, which enter the passenger stations of the large towns, but are otherwise quite independent of the main lines used for the long-distance traffic, were originally connected with the main lines immediately before the entrance of the station. This arrangement had the disadvantage, that at this end of the station it was accordingly only possible to receive or dispatch one train at a time in either direction, and this hampered not only the work at the station, but also the traffic on the main lines going to the station. Hence it is now the practice, whenever large stations are reconstructed, to keep the track for the short-distance traffic separate from the main lines at the entrance to the station; in the latter separate platform are provided for each direction and it is then possible to receive and dispatch at one and the same end, or at both ends, at the same time, trains from or to various directions.

Such a scheme has been fully carried out in Austria at Lemberg station (fig. 4), Austrian State Railway; it is at present proposed to proceed in this way in the case of the reconstruction of a number of large stations on the Hungarian State Railway, for instance at Szolnok (fig. 5), Kassa (fig. 6) and Zombor (fig. 7).

The dispatch of trains can also be facilitated, as at many stations of the Austrian State Railway, by having an island plat-

form, with bays or projecting platforms at each end, which are used for the departure and arrival of short-distance trains. Such an arrangement is to be found for instance at Bischofshofen (fig. 8) and at Salzburg (fig. 9).

According to information supplied by the administration of the Syzran-Viazma Railway (Russia), the tracks used for the long-distance traffic and those used for the short-distance traffic are not kept separate at the large station but the tracks are grouped in sets according to the direction of the trains. The individual separate

Budapest stations.

groups are used for all the trains of the same direction.

The administration of the Riazan-Ural Railway (Russia) states that at their larger stations the short-distance traffic has no special set of tracks reserved for it, as it is comparatively unimportant; they are satisfied with having one special track for the traffic at the station in question, generally in the form of a dead-ended siding separate from the other platform sidings. Separate arrival and departure tracks are of course provided for the long-distance traffic.

The same arrangements are to be found on the Russian North Western Railway.

On most of the railways in the other countries to which our report applies, which we have not yet mentioned here, the short-distance traffic is at an early stage of its development, so that it has not yet been necessary to provide any special installations for it.

Question 1-*b*. — *Are the suburban tracks arranged so as to reduce shunting operations to a minimum? Have you for instance adopted, as the solution, end loops at certain stations, as at Boston station (U. S. A.)?*

As the preceding information shows, installations of different kinds, for dealing with the suburban traffic, are to be found on the railways of the countries to which our report applies. At some stations, the short-distance traffic is operated on the same station tracks which are used by the long-distance trains; at other stations, there are separate departure and arrival tracks for the long-distance traffic and again separate tracks for the short-distance traffic.

Then there are sections which carry short-distance traffic only, but with their lines joining the main lines used for the long-distance traffic immediately in front of the chief stations; and their traffic enters the stations on these main lines. Finally and quite recently, there are also lines used for short-distance traffic, which have their own tracks right into the stations.

The trains for this short-distance traffic are in all these cases so arranged that it is unnecessary to alter the order of the carriages at the station which forms the ter-

minus of the line in question. The locomotive and the luggage van behind it are uncoupled from the head of the train, and then coupled up again at the other end; the train can then at once be used for the return journey.

If the same locomotive is not used for the return journey, that locomotive and

station.

dises = Sidings for goods trains. — Voie de tiroir = Draw-out track.

the luggage van are in some cases left at the end of the train which is to depart, until another locomotive and luggage van have been coupled up to the train and the train has departed.

The latter procedure is naturally only advisable, when very little time is available between the arrival and the departure of the train. In other cases, at most of the large stations the locomotive is transferred by means of a turntable, a traverser or a simple cross-over to an unoccupied track, so that it can then go either to the locomotive sheds or to the head of the train it is to haul.

In a few cases, matters are arranged so that the luggage van is at the head of the train when this is running in the one direction, and at the tail when it is running in the reverse direction. It is then unnecessary to shunt the luggage van, and on lines of minor importance the locomotive in such cases runs backwards in the one direction.

Some short-distance trains, which only have 5 to 10 minutes at the large stations between arrival and departure, have two luggage vans, one at the head and one at the tail of the trains, and these are used alternately for the luggage according to the direction of running. In this case, it is only necessary to shunt the locomotives.

The solution adopted in Boston, underground end loops being used for the local trains, has as yet not been applied in the countries with which our report deals.

An arrangement of loops similar to that in use at Boston is proposed for the new Budapest stations, as shown in the diagram figure 3. A double-track loop passes round the sorting station, which is connected with the sidings at that station. Similarly, figure 10 shows the general arrangement of an auxiliary station with the sorting station belonging to it, and also the locomotive sheds and the other installations not in direct connexion with our subject. The arriving trains run round the loop on to the sidings on

the departure side, and are at once ready for starting; shunting operations are in this way avoided.

Question 1-c. — *How are the tracks arranged so as to make it possible :* I. *To change locomotives quickly;* II. *To add or take off carriages;* III. *To make up passenger trains, or bring to the platform train made up on a special set of sidings?*

I and II. — As already mentioned, at terminal stations the locomotives of the trains which have arrived are transferred by means of a turntable or traverser or cross-over at the end of the platform track to an unoccupied track from which they can reach the locomotive sheds.

Turning the locomotives by means of turntables is a troublesome operation which is always becoming more difficult owing to the continual increase in the length of the locomotives.

The use of traversers, whether at rail-level or sunk, is troublesome at stations where there is much traffic, and even becomes dangerous if the traversers are not accurately adjusted.

If cross-overs are used, a rather large fraction of the utilizable length of the station tracks is lost, which is of considerable importance as the station halls are of limited length.

In spite of this, many of the older stations have to depend on such devices exclusively. Thus we find turntables at the inner ends of several Vienna stations. At the Budapest West station there are however several at the outer end of the station hall; they are used for adding or taking off individual carriage, and will be removed in the course of the alterations which are now being carried out.

At Budapest West station there are in addition intermediate tracks between the platform tracks, which are used for locomotives running out of the station.

In consequence of these difficulties the devices in question have not been put in at some of the most recent terminal stations. Thus for instance the sidings of the new Triest station of the Austrian State Railway (fig. 11) are simply dead-ended, without any such provision. The locomotive of a train which has arrived consequently does not become free until the train itself has been taken out of the station.

In the countries to which our report refers, the railway administrations are generally speaking of the opinion that this problem can only actually be wholly solved at through stations, where the locomotives can run to the sheds on separate tracks specially provided for the purpose.

Such arrangements are now in the course of construction at many stations; in Austria for instance at the Salzburg (fig. 9), Linz (fig. 12), Pilsen (fig. 13) and Budweis passenger stations; in Hungary at Szolnok (fig. 5), Győr (fig. 15), Püspökladány (fig. 16), Zombor (fig. 7), Czegléd (fig. 17), Kassa (fig. 6), Ersekujvár (fig. 18), Vinkovce (fig. 19) and Királyháza (fig. 20) stations; in Russia at Wilna station (fig. 21).

In order to make it possible to provide locomotives quickly for the departing trains, it is also necessary that the locomotives should be able to reach the head of the departing train from the locomotive sidings by means of tracks which must be

kept clear, without interfering with the main lines. It is consequently very desirable to have the locomotive sheds as near to the passenger station as possible.

In order to be able to add or take off individual carriages, dead-ended sidings are provided at the newer stations between the platform tracks; the spare carriages stand on these sidings ready for use. These sidings make it possible to add or take off single carriages in a very short time, without increasing the normal time the train stops and without interfering with the arrival or departure of other trains.

III. — At most of the large stations which we are considering here, even in those cases where larger alterations were made, no provision could in many cases be made for facilitating the making- up of trains on the platform tracks, either because no room was available, or because other difficulties were in the way. The installations made consequently varied with the local conditions.

At those stations where passenger trains are made up or taken apart, one had in most cases to be satisfied, when enough land was still obtainable, to provide sufficient sidings for storing and shunting the trains. These sidings must be connected with the tracks used for the mail and quick-freight operations and with the locomotive sidings..

At the older stations, particularly if they are terminal stations, when trains are made up or taken apart it is often necessary to cross the main arrival and departure lines; this endangers the safety of the working and much reduces the working capacity of the stations.

This disadvantage could be overcome by having the sorting tracks raised or lowered where they cross the other tracks; but in many cases, for instance at the Vienna and the Budapest stations, this can not be done as sufficient length is not available.

In order to prevent this crossing of the main lines it is then necessary, as for instance at the Budapest East and West stations till the new stations are built, to increase the number of the sidings for making up and shunting the trains, both on the departure and on the arrival side.

Particular attention has to be drawn to the advisability of having sidings also on the arrival side, to which the trains can readily be taken without crossing the main lines. The moving of the trains to the departure side, during which it is impossible to avoid crossing the main arrival and departure lines, must be effected at times when trains neither arrive nor depart, and when consequently the main lines are free. The sorting operations in connexion with the trains are in most cases carried out on the departure side.

At terminal stations with much traffic, the only complete solutions is however the construction of sorting stations, designed for the purpose, which should be as near to the passenger station proper as possible and should be located between the main lines, so that when the trains are dispatched or received the main lines are not crossed.

The last condition was fully taken into consideration in designing the new arrangements at Budapest (fig. 10). The sorting and shunting sidings are to be placed near the auxiliary station, also the locomotive sheds for the passenger trains, and the installations for mails and quick

freight. The loops will reduce shunting operations to a minimum, because both the long-distance trains and the short-distance trains are generally definitely made-up trains.

Special readily-accessible sets of sidings or only single sidings, as may be required, are provided for taking the mail, parcel and luggage vans, the saloon carriages and the sleeping and dining cars; the locomotive sheds, which are to be exclusively for the passenger traffic, are to be in the middle of the whole installation, so that the distances the locomotives have to cover may be reduced to a minimum.

As already mentioned, such stations are to be constructed on the two opposite sides of the Budapest town limits. As a rule, all the passenger trains coming from the north, after passing the three through stations, will be taken apart and turned round at the south auxiliary station or the sorting station connected with it. In addition the tracks are designed so that international or other through trains, after their locomotives have been changed with as little delay as possible, can continue in any direction; all these arrangements will probably make it possible to receive and dispatch about four times as many trains as at present inside the twelve hours within which the greatest part of the Budapest passenger traffic is operated, which at present amounts to nearly 300 trains per day.

It must also be mentioned, in connection with this question, that various measures have also been adopted in the other countries with which this report deals, in order to accelerate the operation of the traffic at the old passenger stations, which are taxed to the limits of their capacity; particularly with a view to reducing the time necessary for marshalling the passenger trains.

Among them we may mention the system adopted in a number of cases, of sending the mail vans and the cars containing quick freight (beer, fruit, live and dead poultry, meat, fresh vegetables, race horses, etc.), which are to be hauled by passenger trains, as quick-freight trains in advance to some junction station, where they are then coupled up to the passenger train during its normal stop.

Question 1-*d*. — *Have you any stations with separate floors, in which the tracks are, either all or in part, either on an upper floor or in a basement, the ground floor being used for different offices (enquiry offices, booking offices, luggage offices, etc.)? In the case of a mixed arrangement, that is to say, when some of the tracks only are at another level than the ground floor, which tracks are at that level and which are on the ground floor? In the case of stations with separate floors, how are the different services distributed between the ground floor and the other floor? What circumstances: topographic location, difficulty of widening, etc., have led to the adoption of separate floors? What advantages do you consider this arrangement to have to make up for the increased amount which as a rule such a station costs to build and run?*

Stations with different floors, such as at Boston or Dresden-Altstadt, where the tracks are on different floors, do not exist on the railways of the countries with which our report deals. No scheme of this kind has ever been seriously entertained. There are even no cases in which some tracks are at street-level, while others

are raised or sunk. There are comparatively few stations at which the tracks are a floor up. The stations hitherto built, together with their sorting stations and the locomotive sheds are at the level of the ground.

Stations with separate floors, in which all the tracks are in a basement, as for instance at the new Hamburg station, also do not exist in the countries with which this report deals.

In the case of the two through stations which it is proposed to build at Budapest inside the city, the tracks at the one are to be above street-level, and at the other below street-level, in accordance with the local conditions.

At the stations hitherto built which are a floor up, all the tracks used in connection with the passenger traffic are on the same floor. Such stations are : In Austria, the Vienna North and the Vienna South stations; also the stations at Lemberg (fig. 4), Pilsen (fig. 13), Budweis and elsewhere; in Hungary, Szeged station (figs. 22 to 25) is an instance. As far as we know, no such stations yet exist in the other countries with which our report deals.

At these stations, the entrance hall and the booking office are as a rule on the ground floor, as well as all the luggage offices and the newspaper and tobacco stalls, etc. The installations for the post-office, the station offices and the exit lobby are also on this floor. The waiting rooms and refreshment rooms are on the first floor, as well as the traffic offices. The arrangements at the Vienna North and Vienna South stations are very similar. At the North station some of the station offices are on the ground floor and some on the first floor.

At Pilsen (fig. 13) the station building is in the middle between the high-level tracks, and the entrance to the station is reached by crossing under them. The capacious entrance hall is on the ground floor, together with the ticket offices and the luggage offices, while the waiting rooms, refreshment rooms and the station offices are at track-level. The middle platform is used for the Vienna-Eger and the Prague-Fürth trains. The island platforms for the other trains and the loops are reached by means of stairs and subways. The tracks for the short-distance trains, for which the station forms a terminal station, are accessible from the front of the station building (1).

At Budweis station the large entrance hall is reached from the front of the station, with the waiting rooms and refreshment rooms adjoining. The three high-level island platforms are reached by a subway and a staircase, along the centre line of the building. On arrival another subway and staircase lead to the exit lobby. The ticket offices and the luggage offices are also in the large entrance hall; the station offices are at track-level.

At Lemberg (fig. 4) several steps lead up from the street to the entrance lobby, in which space is provided for the mail and the newspaper traffic. This lobby leads to the capacious entrance hall, where the ticket offices and the luggage offices are; from this wide corridors lead to the right and left to the waiting and the refreshment rooms.

(1) See the pamphlet *Oberbau, Bahnhofsanlagen und Eisenbahnhochbau*, by Hugo Koestler, privy councillor to the Railway Ministry, from which some of the particulars concerning Austrian railways have been extracted.

Seven subways lead from the ground floor to the platforms. Three of these subways, with two staircases each and separate entrance and exit, are provided for passengers of the first, second and third class respectively. Arriving luggage, departing luggage, mails and quick freight each have one subway provided for them. To the right of the entrance hall is the exit lobby, where the exit subway and the subway for the arriving luggage end. In the left wing of the first floor there are private waiting rooms for the Royal family, with a private entrance and a private staircase from the street. In the right wing, at track level, there are the station offices and staff offices. A special building, directly accessible from the platforms, is provided for dealing with the mails.

At the Szeged high-level station (figs. 22 to 25) subways are not yet in use. The entrance hall is at street-level, and from its right and its left convenient staircases lead up to the tracks; it contains the ticket offices, the luggage offices, the newspaper offices and the police office. The way out is through a special lobby with special staircases leading down to the street. On the first floor, that is at track-level, there are the waiting and the refreshment rooms, the traffic and the other service offices. Here are also the offices for the mails and for the quick freight, which are made accessible from the street by ramps.

The reasons which lead to the construction of high-level stations, vary according to local conditions. But generally speaking it can already now be recognized that it is not advisable to build stations at street-level inside towns of larger or of medium size, if these towns are capable of further development; it is better to build the stations below or above the street-level.

This is very advisable in the interests of the public traffic and of the municipal administration, no matter whether it is a question of a through station or of a terminal station; for only if this condition is observed can a station be located in the middle of a town or very near it.

When matters are so arranged the streets can pass either above or below railway track, and both the street traffic and the railway traffic can be operated without interfering with the other.

On the other hand if the stations are at street-level, the wide railed-in spaces they occupy practically cut the town in two and not only obstruct the street traffic but impede the development of the whole town.

It is true that level-crossings, which would obstruct the traffic at large stations, can be done away with by putting in underbridges or overbridges; but when the stations are at street level the necessary approach ramps are a disadvantage both to the street and to the traffic.

Besides these general reasons, which are probably of preponderating influence in the case of any large town, special local conditions have in most cases affected the choice made.

In order to indicate a few of these, we will as an instance describe how some of these stations became developed.

The city of *Pilsen* is one of the large industrial and commercial centres of Bohemia, at which many railway lines intersect. These lines were built at different periods and by different owners. The station of the first railway, the Prag-Fürth

line, the so-called "West" station, was built in 1862; while the Vienna-Eger and the Pilsen-Priesen lines were built in 1868-1876. The West station and the separate station built for the Pilsen-Priesen line, were it is true extended as much as possible to suit the growing traffic; nevertheless in 1895, when all these three railways were incorporated in the State Railway system, the stations no longer sufficed for their work. As however both stations had in course of time become surrounded by large factories and other valuable buildings, it would have been excessively expensive to enlarge them. In order to meet the growing industrial requirements, the whole railway installations were rearranged. The two old altered stations were replaced by a large new passenger station (fig. 13); the old workshops of the Pilsen-Priesen line were replaced by a large new goods yard. The two workshops as well as the sorting stations were located outside the city. The lines going to the station, which cross parts of the town where there is much traffic, as well as the passenger station itself, were all built at a high level.

Budweis station was a joint passenger station used by two privately-owned main lines, Vienna-Eger and Linz-Budweis, while the goods traffic was dealt with at two separate stations. After these lines had been incorporated in the State system, the great increase in the traffic which had in the meantime taken place made the complete reconstruction of the stations necessary. The passenger station and the tracks entering it were raised 6 metres (19 ft. 8 in.), in order to allow the busy streets to pass below them. On the other hand, the goods and sorting stations were left at street-level, in order to lay out the line more favourably, but in doing this, level crossings were avoided.

At *Lemberg* the Karl-Ludwigs Railway and the Lemberg-Czernowitz-Jassy Railway each had a separate station built in their time. After the two lines were incorporated in the State system, the first station was converted into a passenger station and the second into a goods station.

Later on these stations were enlarged, but as the traffic grew they no longer sufficed; they were accordingly entirely rebuilt by the administration of the Austrian State Railway. Of the old installations only the goods station remained, while a new station, connected with a corresponding sorting station, was built for the passenger traffic.

The passenger station was raised over a length of 1,000 metres (1,094 yards) above the level of the other stations, chiefly in order to make it possible for the lines which connect the other stations to pass under the passenger stations. Another object of this arrangement is to give the passengers readier access to the different platforms (fig. 4), as already mentioned.

The station at the city of *Szeged*, which is the second largest city in Hungary as regards population, also had to be constructed at a high level, principally on account of the Tisza bridge, which is in its immediate neighbourhood and is at a considerably higher level than the streets of the town. This arrangement makes it easy for the streets and roads to pass under the railway.

In the case of the proposed reconstruction of the Budapest stations, the interests

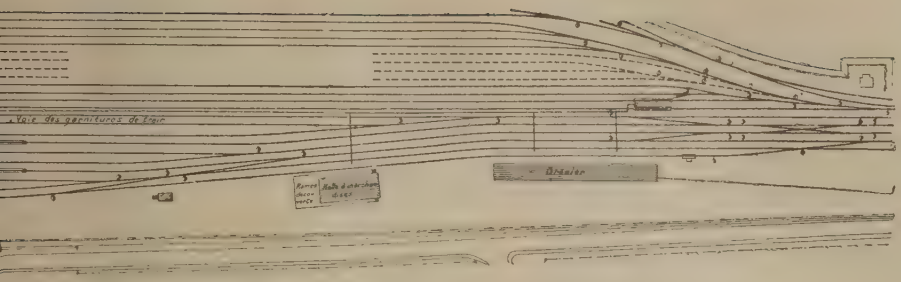
of the city traffic and of the municipal administration in the first place led to the selection of a high-level track, and to that of a low-level where geographical and other conditions made this necessary.

QUESTION 1-*c*. — *Have you adopted the solution of "double platforms", applied more especially at stations on the French Northern Railway ?*

Such "double platforms" are hardly in use in the countries with which our report deals.

At Riaj station (fig. 14) on the Riazan-Viazma Railway (Russia), there is a kind of double platform, but not arranged as at St. Omer and other stations on the French Northern Railway.

The arrangement at Riaj station is shown in figure 14; each of the two sides of the double platform is used simultaneously for receiving two trains coming



station.

irs = Sleeping quarters. — Bâtiment des voyageurs = Passenger-station building. — Voies des trains de marchandises
handises = Goods shed. — Grenier = Grain-store. — Bâtiment de la poste = Post-office building.

of goods trains. — Rampe à charbon = Coal ramp. — Dépôt des locomotives = Locomotive shed. — Voies des locomotives
handises = Goods sidings. — Halle à marchandises = Goods shed. — Voie industrielle = Works line. — de = from — à = to.

from different directions. Thus for instance on track I a main-line train can arrive from Riazan, while at the same time another arrives on track V from Viazma. At the same time, on the other side of the platform, a main-line train can arrive from Koslow on track II and another on track III from Syzran.

Question 2. — *Please describe the mechanical appliances you have, either at the stations with separate floors, or at the stations at one level: a) For the conveyance of luggage (lifts, motor tricycles, travelling endless belts, etc.); b) For the conveyance of passengers (lifts, travelling inclines, moving staircases, etc.); c) To your answer please add particulars and drawings of the appliances mentioned under a) and b).*

In the case of stations at street-level, in the countries with which our report deals, mechanical appliances have not hitherto been used for the purposes mentioned. As a rule hand-carts with three or four

wheels are used for conveying luggage from the luggage offices to the luggage vans of the trains.

In the case of some of the high-level stations the luggage is raised from the luggage office in the ground floor to track level and vice versa by means of electric lifts. The hands-carts which are loaded with the luggage are placed into the cage, lifted and then run to the luggage van; or conveyed in the same way in the opposite direction to the luggage-delivery office. Such a lift is in use at Szeged station; it is however not located in the entrance hall but at the chief platform between the station building and the first track.

A special installation of this kind exists at Wilna station (fig. 21) on the Russian North Western Railway, where the tracks are at street level; between them there are island platforms, which are connected with each other by a subway. The hand-carts loaded with luggage are lowered to the level of the subway, and then pushed to the lift of the platform required and there raised. Arriving luggage is dealt with in the opposite way. Motor tricycles, travelling endless belts and mechanical devices other than those mentioned have hitherto not been used for the conveyance of luggage.

Neither lifts nor travelling inclines nor moving staircases are used for the conveyance of passengers.

At the through stations which are at street-level the trains are generally reached from the waiting and refreshment rooms by crossing the lines, and the exit lobbies are reached from the trains in the same way. Passengers are only allowed to cross the lines at certain paved crossing places. At busier stations, low wire-fences are put up between the tracks, except at the crossing places, so as to compel the public to keep to the latter.

At larger stations which are at street-level, island platforms are provided, as the large number of trains makes crossing the lines dangerous.

In most cases, the main platform is next to the station building, and from it a staircase leads down to a subway, which crosses below the rails and is connected with the different island platforms also by staircases.

In the case of terminal stations at street-level, the passengers reach the intermediate platforms directly from the end cross platform. In the case of terminal stations where there is no end cross platform, subways and stairs are used.

At some of the older high-level stations, for instance Vienna North, Szeged, etc., there are as yet no subways, and the island platforms can only be reached by crossing the line.

At Budapest West station, there is a subway near the hall which has a special object. It connects the quick-freight receiving and dispatching offices, which are at the two opposite sides of the building. Its chief object is to be able to transfer arriving transit quick-freight to the departure side; it also has the object of facilitating the transfer of some mail matter, particularly newspapers and articles of value, from the post-office which is at the side of the station to the mail vans which are already attached to trains about to depart. Finally, the subway is also used for taking the electric accumulators used for train lighting from the charging house to the platforms and vice versa. The subway is 4 metres (13 ft.

1 $^{1}/_{2}$ in.) wide and 2·5 metres (8 ft. 2 $^{7}/_{16}$ in.) high, and has several lateral branches which lead to the points where quick-freight is dispatched and received, where accumulators are charged and where the mails are dealt with. The tunnel and its branches are connected with the different places by a number of electric lifts.

B. — Large goods yards

Question 1. — *Are the sidings at some of your sorting and shunting yards arranged so as to ensure the continuity of the movement, in one given direction and consequently without any reversal, of the cars to be dealt with, from the time an arriving train is received until a train is made up and ready to leave?*

Question 1-*a*. — *Are these sidings on a continuous incline so that the cars can be sorted by gravity without requiring a locomotive, or do they consist of successive sets of sidings on the flat, commanded by saddle-backs on to which the trains are pushed by the locomotive? Are there successive gridirons which allow a train to be classified according to destination and on which the making up of a train can be completed?*

1. — The sorting and shunting yards of the railways with which our report deals, were constructed in their time according to many different plans and have been extended and altered in many different ways since.

Sorting and shunting yards, which are arranged so as to ensure the continuity of the movement of the cars, from the time of their arrival at the yard until they are made up into trains ready to leave, without the wagons having to make any unnecessary movement, are only of quite recent introduction in the countries which we are considering. The construction of such yards, which make very economic working possible, would in most cases require a very large capital expenditure, which it is true would in course of time be counterbalanced by the advantages obtained; but the capital required is not always available.

In those cases in which the sorting is to be not only according to direction but also according to station, care would have to be taken that the arriving trains can at once pass from the reception sidings on to the sorting sidings following the reception sidings; the cars are then to pass on to the gridiron and then on to the departure sidings, all these sidings being arranged longitudinally so as to form continuations of each other, so that the ready train can then at once start from the departure sidings.

But even with this arrangement, which might be considered perfect, the superfluous movements of the cars, while they arrive and are sorted and leave again, can only then be wholly avoided if the yard is divided into two separate halves, quite independent of each other and each used for one chief direction.

The arrangement would accordingly have to be such, that for instance in order to sort the goods trains coming from the north and going to the south there would be one special separate sorting yard, consisting of the four sets of sidings described above; and for the goods trains coming from the south and going to the north there would be another similar yard with

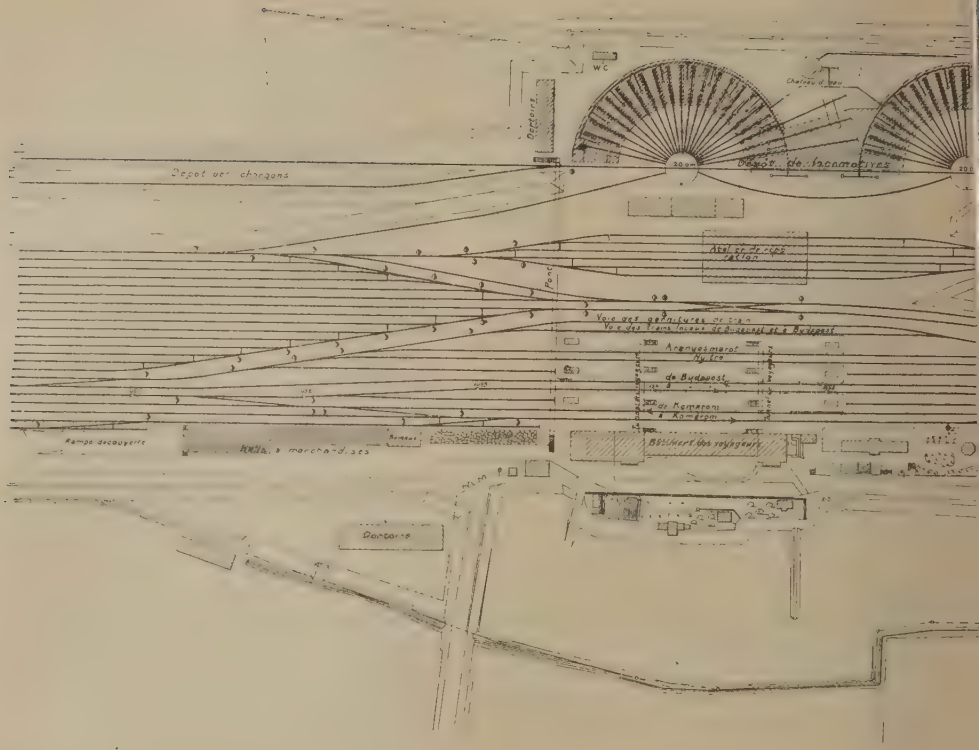

Fig. 1

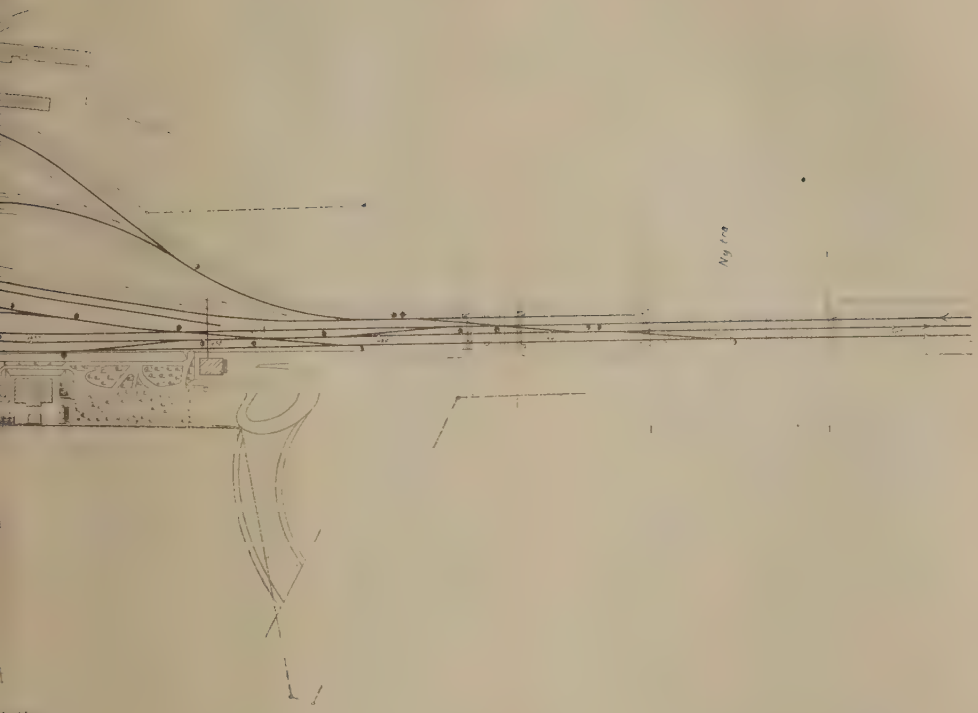
motives = Locomotive shed. — Atelier de réparations = Repair workshops. — Pont = Bridge. — Voie des garn
Budapest. — Bâtiment des voyageurs = Passenger-station building. — Passage en dessous. = Subway. — de =

the sidings arranged in the reverse direction.

Such sorting and shunting yards may with full justice be described as perfect; but as far as we know there are only a few on the whole continent of Europe and these have only been built very recently. The high cost of construction, the great technical difficulties which have often to be overcome when building such yards several kilometres in length, if the country is at all undulating, in order to cross highroads and watercourses, are generally great obstacles to the construction of such extensive installations. In large cities, these difficulties are still further increased by the great cost of the land, quite apart from the fact that the large empty spaces required are as a rule only to be found at greater distances from cities.

These are no doubt the reasons why up to the present very few such sorting and



tation.

s shed. — Bureaux = Offices. — Dortoirs = Sleeping quarters. — Château d'eau = Water-tower. — Dépôt de loco-
ing for made up trains. — Voie des trains locaux de Budapest et à Budapest = Track for the local trains to and from

shunting yards have been constructed. Moreover, it is not advisable, unless there is very much traffic, to expend the large sums of money which such large installations involve, and even at the most important junction points in the countries with which our report deals, the need for such installations does not everywhere exist. At some otherwise important junctions, operations can still be carried out sufficiently economically by simpler even if imperfect installations. As a general rule however the administrations have endeavoured to arrange the larger sorting and shunting yards which they have built in recent times, or are going to build, in such a way that loss of time and unnecessary movement of the cars are avoided as much as is possible under the existing local conditions, and considering the needs of the traffic.

1-*a*. — In the countries with which our

report deals, no single sorting and shunting yard has yet been constructed, which is wholly on a continuous incline, so that the cars of the arriving train could be sorted, without using locomotives, and arranged in trains on the departure sidings.

Most of the older sorting and shunting yards were constructed in their time on the flat or nearly so, so that the shunting operations are carried out by locomotive power. The trains arrive on the sidings which serve both for reception and for departure sidings, the locomotive and the brake van are removed; the cars are then sorted and shunted on to the corresponding siding of the sorting-siding group by a shunting locomotive. The cars collected on each sorting siding, if no further sorting is required, are then shunted on to the departure sidings and the train is then made ready for starting by coupling on the locomotive and the brake van.

At those sorting and shunting yards where the main line can be directly reached from the sorting sidings, the train often starts from the sorting siding.

If it is also necessary to sort according to station, this is as a rule effected at the other end of the sorting sidings.

This system of sorting according to station is not economic, as two locomotives are required, and many operations. The process is tedious and the cars can not be properly utilized and dispatched quickly enough, as two locomotives can only shunt 500 to 700 cars in twenty-four hours.

At the Rákos-Rendezö sorting and-shunting station, which deals with the traffic of the goods station of the Budapest West station, and where about 2,700 cars arrive per day, the sorting sidings are divided into four groups, and it is consequently possible to carry out several sets of shunting operations simultaneously. Seven or eight locomotives are used for this purpose.

The same state of affairs also exists at many of the older Austrian and Russian sorting and shunting yards; for instance in Austria at Stadlau, Trübau, Floridsdorf, etc., and in Hungary at Ersekujvár, Györ, Komárom, Szeged, Nagyvárad, Kassa, Zsolna, Kuttka, Püspökládany, Czegléd, etc. Another great disadvantage of this method, besides those already mentioned, is that it is impossible to remove the row of cars which require sorting, from the reception sidings and take them to the inclines, if in the meantime trains are arriving or departing. Finally reasons of safety make it in most cases inadvisable to do sorting by stations at the opposite end while sorting by direction is going on at one end.

In order to make it possible to carry out both these sorting operations simultaneously, the sorting sidings would have to be made much longer than required for the longest trains dealt with. This would however in most cases materially increase the cost of construction.

In order to make it unnecessary to interfere with the joint reception and departure sidings during shunting operations, draw-out sidings were provided at both ends of many such sorting and shunting yards. The greater number of the modern and more suitable sorting and shunting yards which at present exist, became developed in course of time out of this original form.

When in consequence of the growth of

*

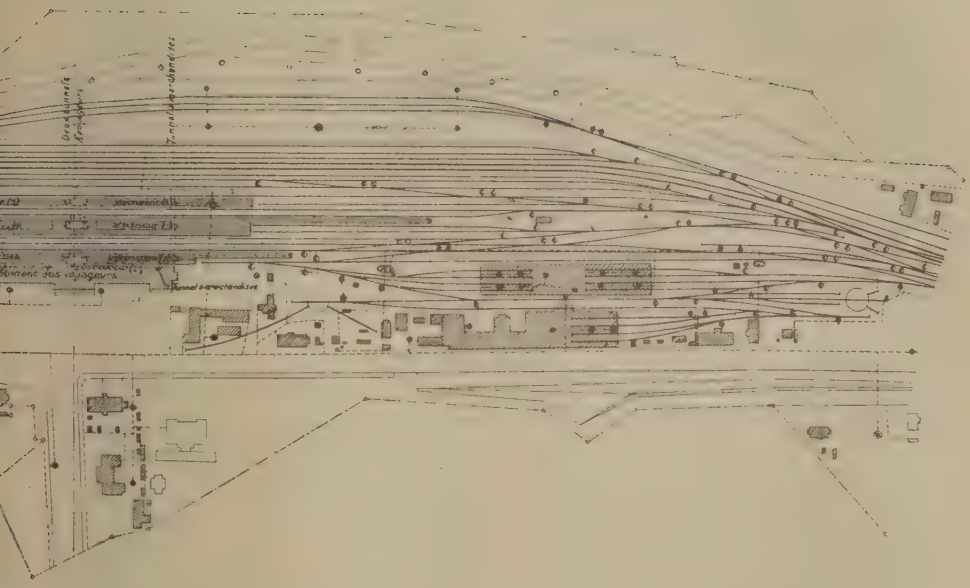
Fig

Explanation of French terms : Bureaux = Offices. – Tunnel à marchandises = Subway for goods. – Deux

the goods traffic or of the addition of new railway lines, the sorting and shunting yards, which were arranged on the flat and for locomotive shunting, were no longer able to cope with the traffic, although the number of their sidings had been materially increased, the administrations were compelled to adopt the English systems, and of the two English systems known, they naturally used that which involved least expense in transforming the old sorting and shunting yards.

It would however hardly have been possible to adopt the system of a continuous incline, and to convert the old yards in this way, without long and serious interference with the traffic, for the inclines must have a gradient of about 8 to 10 per mil; if for instance the total length of the yard were 2 kilometres (1 mile 427 yards); then the one end would have to be raised 20 metres (22 yards). If the yard were on the flat or nearly so, this would involve very great expense and all traffic would have to be stopped while the work was being executed.

Consequently, in all cases where the old level yards, intended for locomotive shunting, were to be altered and gravity shunting used, the second English system was adopted, namely that of saddle-backs; the existing sorting sidings can then in greater



tion.

= Two subways for passengers. — Bâtiment des voyageurs = Passenger-station building. — Ascenseur = Lift.

part remain in their original position on the flat, and it was only necessary to raise the draw-out track at the one end of the station to the height of the incline, that is to 1 or 2 metres (1 to 2 yards); the end of the sorting sidings connected with the draw-out track also requires a gradient of 3 to 5 per mil to be given to it.

These alterations can be made without particular difficulty and without material interference with the traffic, and cost comparatively little. But installations modified in this way can only satisfy the requirements of a modern sorting and shunting yard to a limited extent.

The row of cars which is to be sorted is then hauled by a shunting locomotive from the reception sidings to the draw-out track, and the cars are then sent from these down the incline to the different tracks forming the sorting sidings, from which the completed trains as a rule depart direct.

Sorting and shunting operations at such yards are more economic and also somewhat quicker than at yards on the flat; thus for instance the same amount of work requires seven to eight locomotives at Rákos-Rendező yard which at Szolnok, where there is an incline, only requires four or five.

Sorting according to station is also

carried out at most of the stations of this kind in this way. At some shunting stations, there are however on the opposite side of the incline, a number of dead-ended sidings in connection with the draw-out track; these are used for station sorting.

Sorting and shunting yards with inclines arranged in this way are to be found, among others, in Austria at Mährisch-Ostrau-Oderfurth, Aussig, Salzburg, Pilsen, Budweis, etc.; in Hungary at Miskolez, Rákos, Szolnok, Dombóvár, Budapest-Ferenczváros (fig. 26), Pozsony, Hatvan, Piski, etc.

A further development in shunting yards with inclines is to be found, for instance in Austria at Oderberg (fig. 27). Here there is a set of secondary sidings forming a continuation of the sorting sidings, and the sorting sidings are divided into two groups, one serving for the cars which require no further sorting, and are accordingly taken from the sorting sidings to the departure sidings, or else can start from the sorting sidings direct, while the second group is used for the cars which still have to be sorted according to station. These cars are then pushed by the shunting locomotive to the corresponding track of the secondary sidings, from which the trains when ready can start direct, or else can be taken to the departure sidings.

This arrangement corresponds more nearly to the principle according to which the movement of the cars during the sorting and shunting operations should be reduced to a minimum and should always be in the same direction. Among others, the larger sorting and shunting yards of the Austrian State Railway, at Oderberg (fig. 27), Strasshof (fig. 28) and Prerau (fig. 29) and Linz, are arranged in this way.

Their chief advantage, as compared with the yards previously described, is that the arriving train need not first be hauled from the reception siding over the draw-out track to the incline; after the locomotive of the train has been removed and the brakes have been taken off, the shunting locomotive placed behind the train pushes it to the top of the incline which is between the reception sidings and the sorting sidings, and the cars then run down from there on to the sorting sidings.

As a rule there are two tracks on the incline, which are connected together. This makes it possible to run down cars from both tracks on to any sorting siding desired; this is for instance the case at Linz, Oderberg, Strasshof and Prerau in Austria, and at Kotchetowka in Russia. At the last yard, there are in addition to the sorting sidings secondary sidings for sorting according to station, and next to the latter there is a second small incline over which the cars which have already been sorted on the sorting siding are pushed by a shunting locomotive on to the dead-ended sidings used for sorting according to station. The cars in this case must, as figure 30 shows, move in the reverse direction while they are being sorted according to station.

It has also to be mentioned that at Kotchetowka yard, as also at several Austrian and Hungarian yards, the one track of the incline is higher than the other, so as to make it possible to use a steeper gradient when weather conditions are unfavourable.

Operations at the last-mentioned yards

are quicker and consequently the rolling stock can be utilized better; consequently they represent a material improvement on the older arrangements.

On double-track railways however, the continual growth of the traffic made it more and more apparent that it was objectionable to have the sorting and shunting yards on one side of the main lines only, and that consequently goods trains arriving on the further main line or leaving by it had each time to cross the other line. As this interfered with the safety and the regularity of the working on the other line, this was obviated at some of the newer yards, for instance in Austria at Linz, Oderberg, Prerau and Strasshof, by having two entirely-separate yards, one being used for sorting the trains coming on the one line, and the other being used for the trains coming on the other line.

It is worth notice that at none of the yards built hitherto on this plan, are the tracks of the two halves on each side of the main lines arranged in quite the same way.

This is due firstly to the fact, that in the case of some of these double yards, the existing old yard, with the tracks suitably modified, was retained as the one half. This part of the yard can accordingly not be constructed entirely in accordance with modern principles, while of course when the new part was built for the trains going in the opposite direction all modern improvements could be adopted.

But even in the case of double yards which are wholly new, the tracks on the two sides were not arranged in quite the same way and made of quite the same extent, as the traffic in the two opposite directions nearly always differed in amount and in nature.

Thus for instance the lefthand set of sidings at *Strasshof* yard, Austrian Northern Railway, has as its chief object dealing with the cars coming from Vienna North station, from the Vienna Junction line and from Donau-Ufer station, as well as those coming from the intermediate stations Floridsdorf, Süssenbrunn and Wagram; the cars are sorted according to their destinations in the north.

Five reception sidings were constructed for the purpose on the left hand side and connected over a saddle-back with twelve sorting sidings. The cars which have been sorted can then at once depart, or if sorting according to station is still required, they can be hauled by a shunting locomotive to a draw-out track in connexion, and then pushed back into one of the three existing dead-ended sidings.

The chief sidings on the right hand side are used for sorting the trains coming from the north so that the transit freight can be taken, without being sorted again in Vienna, to the Vienna Junction line and to the Donau-Ufer station; while the local freight, as soon as it arrives in Vienna, can at once be taken to the corresponding stores or warehouses without any shunting operations which would involve loss of time. The sorting sidings on the right hand side are only twelve in number, instead of fifteen.

At the *Prerau* yard the sorting sidings in the one half yard form a continuation of the reception sidings; in the other, they are next to them. In the latter older set of sidings, the cars of the arriving train must accordingly be pushed back on to

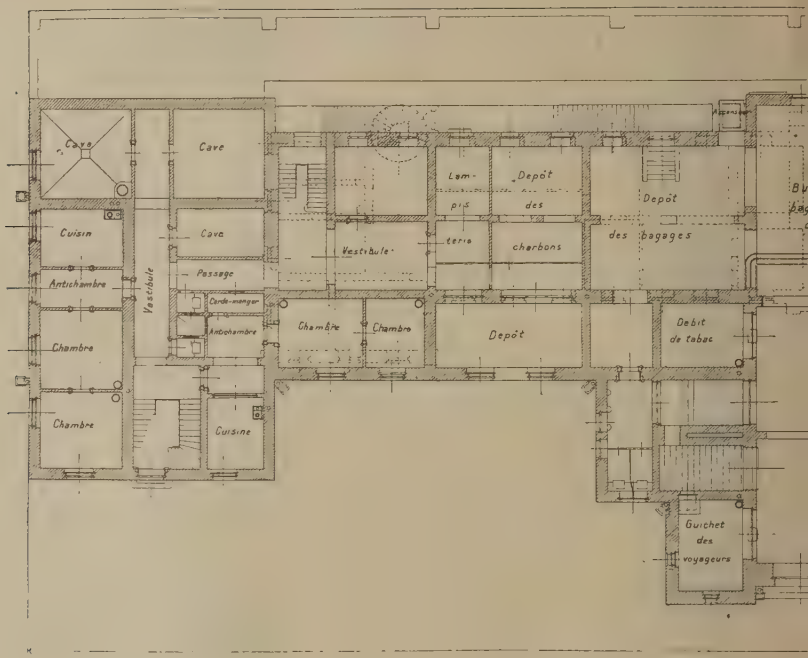


Fig. 22. — Passenger-station

Explanation of French terms : Cave = Cellar. — Cuisine = Kitchen. — Antichambre = Antechamber. room. — Dépôt des charbons = Coal store. — Dépot = Store. — Dépôt des bagages = Cloak roon room. — Office = Servants'hall. — Bureau des bagages au départ = Office for dispatching baggages. the draw-out track of the saddle-back before they are sorted.

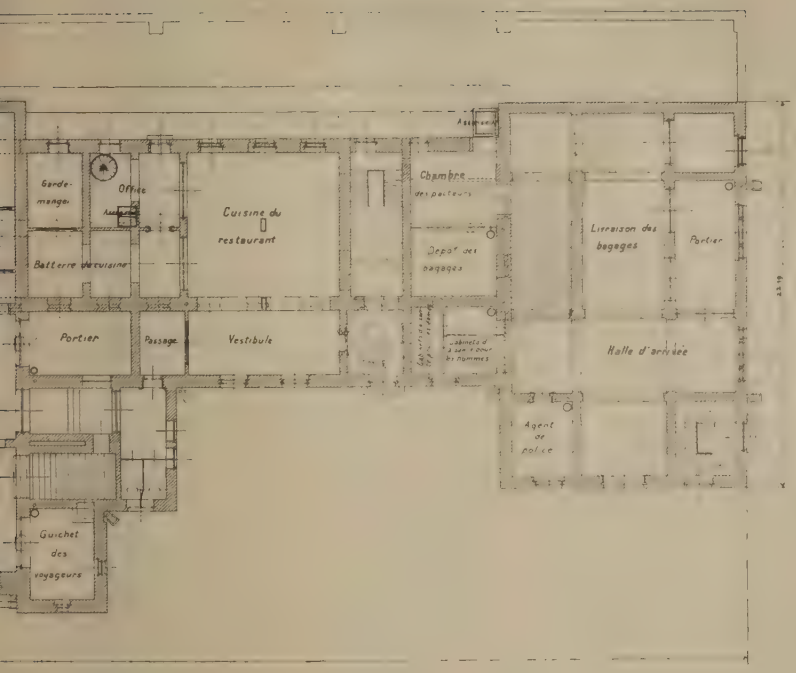
At *Oderberg* among the sidings provided on one side of the main lines, for the North-South traffic, the sorting sidings are connected with an incline which forms a continuation of the reception sidings. They are divided into two sets next to each other, the shorter set, without incline, is connected with the set of sidings intended for sorting according to station. The sidings for the South-North traffic are on the other side of the main lines; as less traffic has to be dealt with there are fewer reception sidings, and in their continuation there are also fewer sorting sidings, from which the trains start. There is no incline on this side, nor are there any special sidings for sorting according to station. This installation, which is quite new, thus entirely depends on the use of shunting locomotives; the reason for this is that most of the trains coming from Vienna to Oderberg are



ation. — Plan of ground-floor.

– Garde-manger = Pantry. — Passage = Passage. — Vestibule = Vestibule. — Lampisterie = Lamp

— Cabinet d'aisance pour les dames = Lavatories for women. — Cabinet d'aisance pour les hommes

going to Prussia and consist of empty returned cars. Only a few of these trains go to the Oderberg auxiliary station and then on to the chief station, and on to the Kassa-Oderberg line, and as consequently shunting operations are but few and also simpler in character, the use of shunting locomotives still gives satisfactory results.

At *Kotchetowka* sorting and shunting yard (Russia) the trains are sorted for the relations Koslów and Saratow to Riasjanj on sorting sidings which form a continuation of the reception sidings, with a saddle-back in between; the sorting sidings are continued into the departure sidings, but without a saddle-back in between. On the other hand, the sorting of the trains going in the opposite direction is effected without incline on sets of sidings which are side by side. The reasons for this difference between the installations for the two directions are partly the local conditions, partly also the fact that the freight traffics in the two

directions are of very different character.

Linz yard, which has already been mentioned, may be included among yards of this type; although some of the arrangements are different, the sorting for the two directions is kept separate.

The Budapest yards are also to be reconstructed on modern principles, in connection with intended reconstruction of the Budapest stations; a new sorting and shunting yard (fig. 10) is proposed, on one side. A saddle-back is to be placed between the reception and the sorting sidings, up which the trains are taken by locomotives. From that saddle-back however, the whole of the work is to be carried out by means of gravity, and the primary and secondary sorting sidings are designed to have gradients of from 5 to 10 per mil. The projected sorting and shunting yard will provide for the general and special sorting and shunting to the chief repairing workshops and to the coal and goods yards, and ample siding accommodation will be provided for cars which require repair, or for cars standing idle at times of little traffic.

Before concluding the consideration of this question, we will mention a few sorting and shunting yards where the usual arrangements were quite impossible owing to the local conditions, such as the proposed auxiliary station at Fiume and the shunting and sorting yards at Budapest-Ferenczáros (fig. 26) and at Dévényujfalu (fig. 32).

The sidings at Fiume, used simultaneously for the passenger, the goods and the shipping traffic, were built near the shore of the Quarnero bay, on marine deposit; they were constructed in successive portions, as the traffic increased. At present however, the station (fig. 33), on the town side is nearly wholly enclosed by hotels, private houses and large industrial establishments, immediately behind which steep hills rise, so that any land required for extending the station could only be obtained by the very expensive method of reclaiming it from the sea.

It was not possible to provide inclines for the existing sidings owing to local conditions; locomotives must therefore be exclusively used. The continual growth of the goods traffic makes it very difficult to sort, according to store and warehouse, the many cars coming from Budapest, and similarly to sort the oversea traffic arriving there, according to direction. The extensions which have at present been begun will probably not suffice; it has accordingly been proposed to build an auxiliary sorting and shunting yard. Owing to the unfavourable conditions mentioned, it will however not be possible to have this yard in the immediate neighbourhood of Fiume and connected with that station. The solution adopted is therefore as follows: the freight arriving at Fiume by sea and going inland is sorted at Fiume station, which is enlarged as much as possible; the goods trains coming from inland to Fiume are sorted at a new sorting and shunting yard near Buccari station, about 10 kilometres (6·2 miles) from Fiume.

Now as this yard is only to be used for the sorting operations in the one direction, the plans could be better suited to the local conditions and requirements. The trains going to Fiume have to leave Buccari station on a special track leading to the reception sidings, which also serve as departure sidings, and are provided at

each end with turn-outs. From here the row of cars is hauled by a locomotive on to a horizontal draw-out track from which the cars are then distributed, by the same locomotive, without using an incline, to the separate tracks of the sorting sidings.

The traffic to be dealt with at Fiume station is divided into five chief sections, and one siding is provided for each section. If the row of cars intended for one such chief section does not require any further sorting according to store or warehouse, it can either start at once from the sorting siding in question, or be hauled to the departure sidings and then start from there. If however the cars which are on one and the same sidings still require further sorting according to store or warehouse, the row of cars is hauled by a shunting locomotive to a second draw-out siding and then distributed from here to the separate tracks of the second set of sidings. The cars collected in this way on the different tracks of the second set of sidings, are then hauled out by the shunting locomotive in their proper order by means of the second draw-out sidings and formed into a train, which then starts either from the sorting sidings themselves or from the departure sidings. These two sets of sorting operations can be carried out simultaneously and independently of each other.

A second track is at present being laid between Buccari and Fiume, where the down-gradient of the railway is 25 per mil. The track which connects Buccari station with the new sorting and shunting yard has a down-gradient, partly of 10 and partly of 25 per mil, while the reception sidings together with all sorting sidings and the draw-out tracks are on the flat. The track from the end of the yard to its junction with the Fiume main line also has a gradient of 25 per mil. Inclines are not provided, partly because this would be very expensive, partly because of local conditions.

The sorting and shunting yard, in spite of the simplicity of the proposed design, will cost about 3 million kronen (£124,800), as in some cases a depth of 20 metres (65 ft. 7 in.) will have to be filled in. It was however necessary to select the place in question for the installation, for the Karst country through which the railway runs is so irregular that the next suitable place was at a distance of 90 kilometres (56 miles), and the interests of the proper operation of the traffic precluded having the sorting and shunting yard at such a great distance from Fiume.

The *Budapest-Ferenczváros* sorting and shunting yard (fig. 26) only differs from the usual type as regards its location. This yard is provided for sorting the traffic from the Budapest goods yards, and from the other sorting yards, for the directions Belgrad, Vienna, Fehring, Fiume and Sarajevo, and also the traffic coming from those directions to Budapest, and also that passing through Budapest. As local conditions made it impossible to have the sorting and shunting yard along side and parallel to the existing station, it was necessary to construct it at right angles to it.

At both ends of the station branches curve off to the set of sidings which serve both as reception and as departure sidings, so that a triangle is formed.

The shunting locomotives haul the row of cars which are to be sorted up the

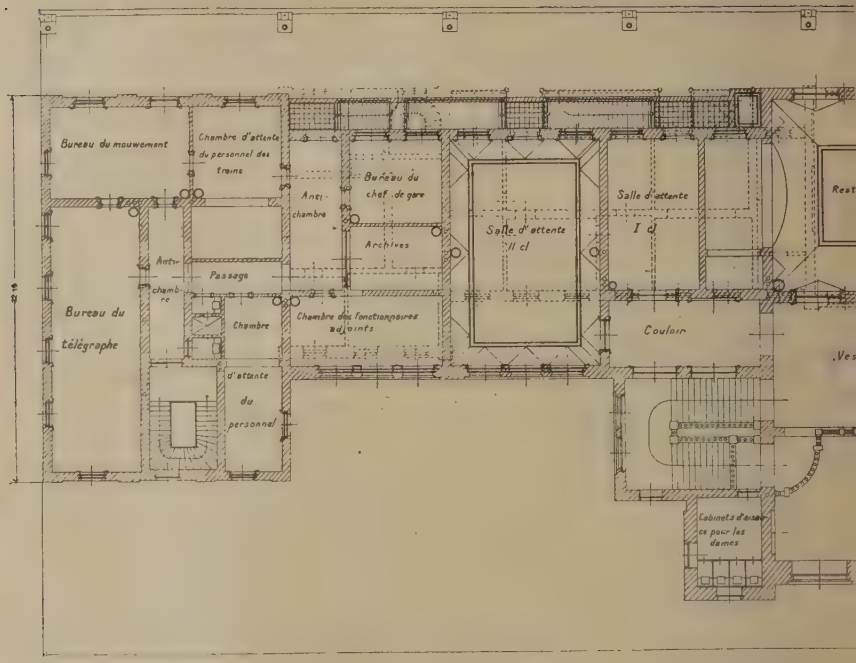

Fig. 23. — Passenger-station buildi

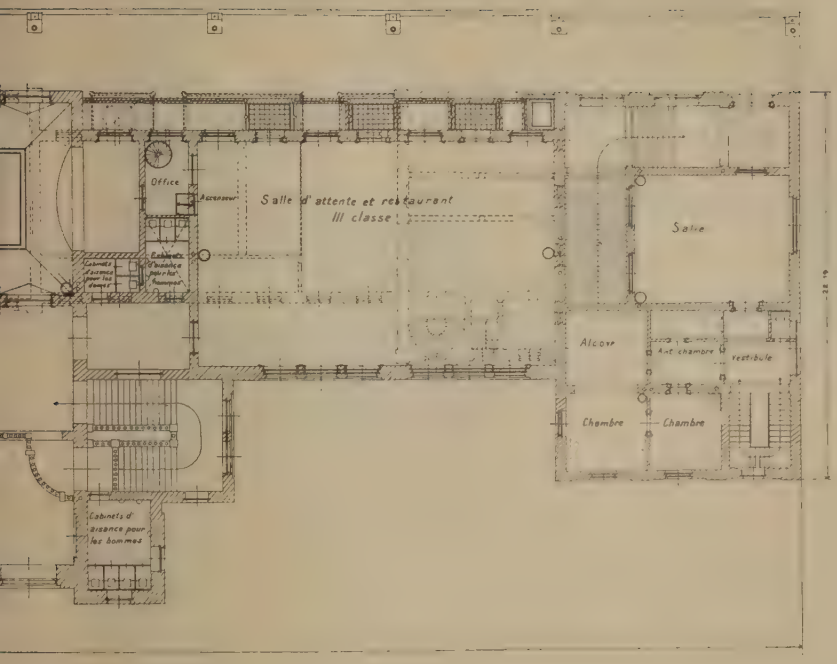
Explanation of French terms : Bureau de mouvement = Traffic office. — Bureau de télégraphe = Telegra staff. — Passage = Passage. — Chambre d'attente du personnel = Waiting room for staff. — Bureau d for assistant officials. — Salle d'attende II cl. = Waiting room, II[nd] class. — Salle d'attente I cl. = Wa Cabinets d'aisance pour les hommes = Lavatories for men. — Couloir = Corridor. — Restaurant de I = Waiting and refreshment room, 3[rd] class. — Office = Office. — Chambre = Room. — Alcôve = Alc

draw-out track of the incline; from this the cars run down the incline to the sorting sidings, which are parallel to the reception sidings. At the other end of the sorting sidings there is a draw-out track on the flat, and a second shunting locomotive can then if necessary in the same way effect the sorting according to station, and then take the sorted rows of cars on to the departure sidings, from which the trains can start.

A great disadvantage of this arrangement is that the trains which have arrived have to be hauled backwards, and that there are no special sorting sidings for sorting according to station; but the chief disadvantage is that the sorting and shunting operations can not be carried out independently of the arriving and departing trains.

Dévényujfalu station in Hungary is between Pozsony and Vienna in the neighbourhood of the Austrian frontier, and the numerous goods trains coming from



ged station. — Plan of first floor.

· Antichambre = Antechamber. — Chambre d'attente du personnel des trains = Waiting room for train are = Office of station-master. — Archives = Records. — Chambre des fonctionnaires adjoints = Room I[st] class. — Vestibule = Vestibule. — Cabinets d'aisance pour les dames = Lavatories for women. — = Refreshment room, I[st] and II[nd] class. — Ascenseur = Lift. — Salle d'attente et restaurant III cl. = Hall.

both directions have to be sorted there. Conditions are here more favourable for an installation which is chiefly on a down gradient, similar to that at Dresden-Friedrichstadt, than for one which is on the flat; while it would have been very expensive to have a yard on a continuous gradient, in a longitudinal direction, as for instance at Nuremberg. The scheme shown in figure 32 was therefore adopted.

There are reception sidings which are used for trains coming from both directions; the rows of cars are hauled from here over a draw-out track having a gradient of 13·5 per mil to sidings having a gradient of 8 per mil; the separate cars are then run by gravity to the sorting sidings, which have gradients of 10·8 and 10 per mil. Those rows of cars which require no further sorting are likewise run by gravity, no locomotive being used, to the departure sidings, which at first have a gradient of 10 per mil, then one of 5 per mil, and are finally on the flat; and

the trains can start from here. The sorting according to station is also carried out on tracks which have a gradient of at first 10 per mil and then of 8 per mil; after the cars have been sorted in this way they are hauled by locomotives to the draw-out track and then pushed back to the departure sidings.

Thus the sorting operations at this station are only partly carried out by locomotives, but it was not possible to avoid repeated movements wholly, as under the existing local conditions it would have been exceedingly expensive to make the sorting yard longer.

Question 1-*b*). — *What system is adopted for stopping and again starting the cars in the two cases mentioned above (hand brakes, sprags, skids, etc.)? Are all the cars which are shunted at yards with continuous inclines, fitted with hand brakes? How is the work carried out when this is not the case?*

Hand brakes, sprags and skids are all used at the yards in the countries with which our report deals.

As regards skids, the Büssing skid is used nearly exclusively; in Russia however the Weber skid and several French skids are also used.

More recently rail brakes have also been used, at Oderberg and Strasshof yards, at the entrances to the gridirons forming the sorting sidings; these seem to be the most suitable means for preventing collisions between cars running at different speeds. When they are used, the inclines can be made higher, and this accelerates the sorting operations. The rail brakes used here are on the Büssing system.

Sprags are nearly exclusively used at the sorting and shunting yards on the flat, where there are no inclines.

At some stations, for instance at several Russian stations, sleepers are laid in front of the wheels of the cars which have been stopped; these sleepers have grooves cut in them, to correspond with the rail heads, and their object is to prevent the cars which are standing still from moving. At some places sand is placed on the rails of the sorting sidings, in order to moderate the speed of the moving cars.

As there are no yards with continuous inclines in the countries with which our report deals, the question concerning the brakes used at such yards requires no answer.

Question 1-*c*). — *What arrangements are adopted for stopping run-aways (chain drags, safety sidings, sand tracks, etc.)?*

No such arrangements have as yet been adopted in the countries with which our report deals. Run-aways are fetched back by the locomotive.

Question 2. — *Have you adopted any arrangement of tracks making it possible to eliminate any interruption of the shunting, sorting and making-up operations owing to the arrival and departure of trains?*

In all cases where local conditions and the resources available made it possible, it was tried to make the sorting, shunting and making-up operations independent of the arrival and departure of the goods trains.

*

for receiving goods.

With this object in view, at sorting and shunting yards on the flat, where locomotives were used for the operations, at least one and in some cases several draw-out tracks were constructed at both ends of the sorting sidings, to the right and to the left of the reception sidings and of the departure sidings, which made it possible to carry out the operations within the left-hand or the right-hand set of sidings quite independently of the arrival and departure of the trains. Attempts were also made to increase the capacity of such sorting and shunting yards in the case of double-track railways by laying special tracks from the nearest station to the yard and from the latter to the next station.

This question was solved in several different ways in the case of the different types of sorting and shunting yards with inclines which have been described above.

At many yards, for instance at Oderberg, Prerau, Strasshof and Kotchetowka, two separate sets each of reception, sorting and departure sidings have been constructed, on which the cars are sorted in the opposite directions, and where trains to or from opposite directions can not cross each other.

At Linz, on the other hand, the cars brought by the trains coming from the two opposite directions move only in one direction during the sorting operations; they are however kept quite separate, and the arrival and departure of the trains is also quite separate in both directions and

stro- Hungarian State Railway Company. — Hangar de réception des marchandises = Sheds

does not interfere with the sorting operations. The same arrangement is also to be adopted at the projected chief sorting station and shunting yard at Budapest.

Keeping the tracks for the passenger traffic and the tracks for the goods traffic entirely separate up to the neighbouring stations also tends to accelerate the goods traffic and to promote the quicker circulation of the cars. The measure is therefore of great importance from the point of view of the better utilization of the rolling stock.

Question 3. — *What importance do you attach to the realization of the different preceding conditions (uniform direction of movement of the cars which are being sorted, independence of the operations of the arrival and the departure of the goods trains)?*

There is no doubt that railway men have for a long time already attached great importance to installations making possible the uniform direction of movement of the cars which are being sorted and the independence of the operations.

Comparative calculations have shown that the extra cost incurred in the construction of such sorting and shunting yards, owing to their greater size, is already counterbalanced in a few years by the saving in working expenses, as with properly-arranged yards the shunting locomotives have to travel much shorter

distances than at yards which are not so well arranged.

It also much more rarely happens that cars or goods become damaged, so that car repairs cost less and there are fewer claims for compensation. It must not be forgotten that in consequence of the smaller number of cars which require repair, the number of cars available is increased. Finally it has to be mentioned that properly-arranged yards are more easily supervised, so that the number of accidents is reduced and a smaller staff is required for supervision.

That in spite of this, some of the older sorting and shunting yards have not been reconstructed is probably due to the fact that this very expensive reconstruction will only pay if the number of cars arriving exceeds 1,500 to 2,000 per day. Then also the different railway administrations are, as already stated, occupied in the first place with satisfying other, more urgent, needs, and the great financial resources which are necessary for reconstructing the sorting and shunting yards can only be raised gradually.

Question 4. — *Please describe the following mechanical appliances, in so far as they are used : a) At sheds where there is one floor only (capstans, cranes, traversers, etc.); b) At sheds where there are several floors (cranes, lifts, conveyor belts, mechanically-operated trucks, etc.).*

At the single-floor sheds of the stations with which our report deals hand-carts only are used for loading and unloading packages. At the larger sheds wall cranes and travelling cranes are in use, all as a rule being hand-operated.

There are but few cases of goods sheds with several floors, the reason being that it is only of late that operations in such high buildings have become simplified by the use of lifts, shoots, wall cranes and travelling cranes, and that a better utilization of space only became necessary in course of time.

We may mention among many-floor sheds those at Triest, Fiume, Brünn, and at Vienna South station.

The *Triest*, goods yards sheds were formerly not the property of the railway, but belonged till lately to the city and to the commercial chamber jointly. They have only recently been acquired by the State, which now operates them. In 1903 a credit of 87 million kronen (£3,619,200) was granted for the extension of Triest harbour; the works are to include twenty-two goods sheds, several of which are to have several floors. In addition, eight warehouses are provided for, several of which are to have three floors and a cellarage underneath; some of these are already in use. The cranes, capstans and lifts used in these warehouses, as well as the turntables, are operated by hydraulic power. The water is at a pressure of 55 atmospheres, and there are three accumulators; it flows through the circuit formed by the high-pressure and the return pipes and only requires filling up to the extent of about 5 per cent.

As a typical instance of these warehouses we will describe the general arrangement of warehouse No. 26. The outer walls are made of rubble masonry and the floors are built with iron girders and concrete jack arches, supported in the case of the ground floor on masonry piers, and it that of the upper floors on iron

columns. The admissible load amounts on the first, second and third floor to 1,800 kilograms per square metre (368·65 lb. per square foot), and on the top floor to 800 kilograms per square metre (163·85 lb. per square foot) and on the outer passages to 600 kilograms per square metre (122·88 lb. per square foot); notice-boards are hung up indicating them. The goods are brought in through the upper doors by a hydraulically-operated wall slewing crane able to lift 1,200 kilograms (2,645 lb.), and the hydraulic lift can deal with the same loads. The latter have cage supports at each floor, and they are all operated from one spot on the ground floor. The operator gives and receives the necessary directions through three speaking tubes. The shaft lining consists of corrugated plate; self-closing shaft doors are however not in use. In addition to the wall slewing cranes there is also a travelling crane working from the ceiling.

The warehouse at *Brünn* station (figs. 34 to 38) also has several floors; and there are electrical lifts, the position of which is shown in the figures.

At *Vienna South station* a new warehouse has recently been built satisfying the most modern requirements, and provision is made for the custom-house operations. The building has several floors, and the cellarage, the ground floor and the upper floors are all arranged for storage purposes. Electric lifts are provided for conveying the goods.

At *Fiume* (see general plan, figure 33) there are a larger number of places for storing goods, most of them being old wooden goods sheds at ground-level and let to private parties. The goods are taken on hand-carts from the sheds to the cars; in some cases hand-operated wall cranes and travelling cranes are available. These old wooden goods sheds are gradually being pulled down and replaced by warehouses with several floors; some of these are built of reinforced concrete, others of brick.

The first larger-sized warehouse of this kind was built at the Molo Marie Valerie; it has three floors, and its dimensions and chief particulars are shown in figures 39 to 42. The railway lines run into the ground floor, and wall cranes and electric hoists are used for conveying the goods up and down. Originally shoots in the form of inclined planes were used for lowering bags; but these occupied much room and gave unsatisfactory results, and were quite recently replaced by vertical helical bag shoots, on the R. W. Dinenthal Company system, which are constructed either by that company or by the Budapest Pumpen and Maschinenfabrik Company. The helical surface as well as the wall lining consist of iron plate, and the bags as they descend can be caught and sorted on any of the floors. Large electric gantry cranes are provided for transferring goods from the warehouse to ships or vice versa.

The arrangement of the other new warehouses at Fiume, Nos. II, III*a* and III*b* is shown in figures 39 to 45. In addition to hand-operated wall cranes there are everywhere electric lifts, the shafts of which are made of reinforced concrete; these lifts are designed for a load of 1,500 kilograms (3,300 lb.) and a rate of 35 centimetres (1 ft. 1 $^{13}/_{16}$ in.) per second.

The iron lift cages are each hung from

two steel-wire ropes, which are always loaded uniformly, and are not supported from the shaft walls, but from a separate iron structure. The doors to the lift only open, if the lift has already stopped behind them, and close automatically as soon as the cage moves. This automatic action can however be stopped by means of a handle, so that the cage passes at points where no loading work is done, and the doors do not open.

The lifts can be operated at every loading point; but hand wheels or cranks are also provided, to make it possible to operate the lifts by hand, should the current fail.

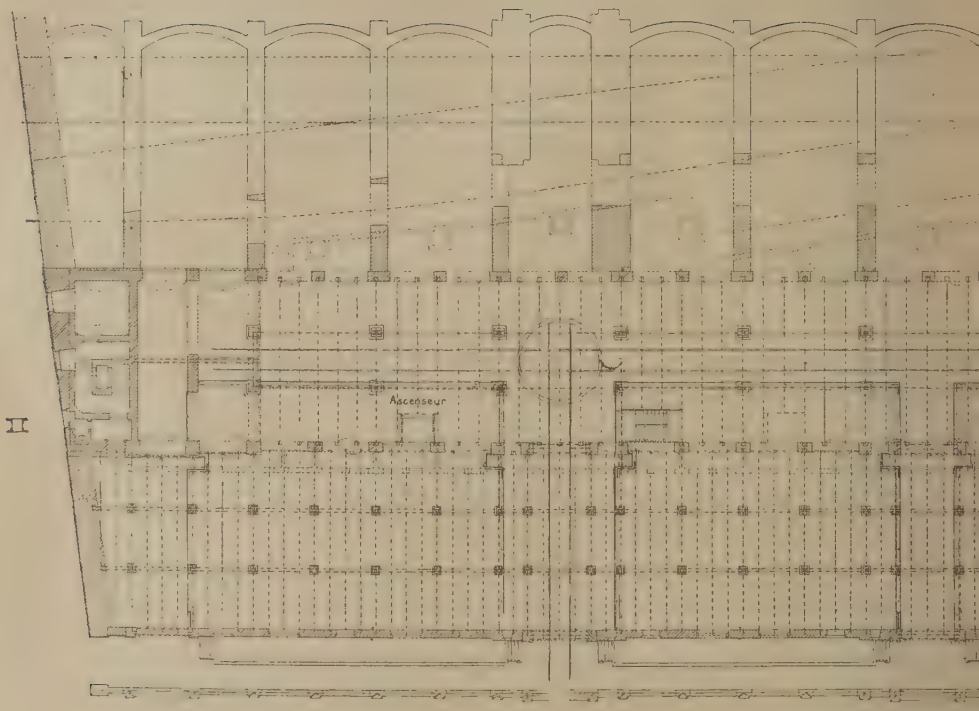

Fig. 34. — Brünn sta

Explanatio

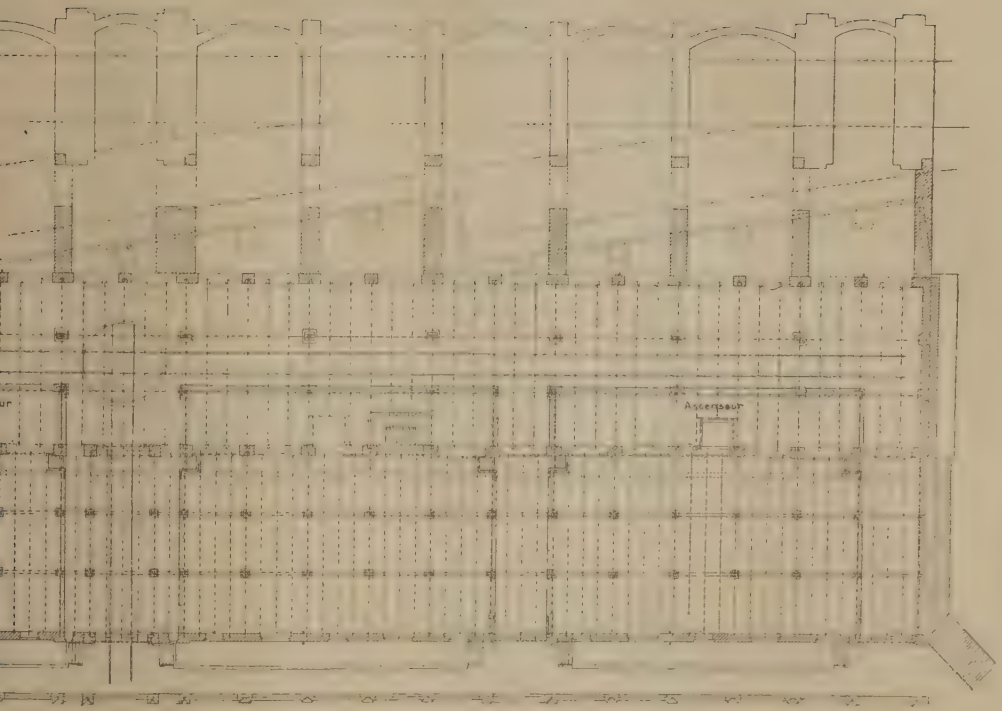
CONCLUSIONS.

When a new large station is to be built, or an old one is to be rearranged, the following rules should be observed :

1° The passenger traffic and the goods traffic should be kept separate, not only within the large station itself, but also if possible between that station and the neighbouring stations;

2° The passenger station should be located as near to the centre of the town as possible; and if the town is a large one, several stations connected by a through line should be constructed;

3° If the town is to have one central station only, a sorting station should be provided near the station proper; and if the latter is in the middle of the town, the tracks should be either above or below



— Plan of ground-floor.

ıseur = Lift.

street-level. If there are to be several passenger stations, it is advisable to provide, at each of two opposite points of the boundary of the town, an auxiliary station which can be used for passenger traffic as well as for sorting and marshalling trains. The passenger stations located inside a town should be through stations and the lines connecting them should be above or below street-level;

4° The installations for the quick-freight and mail traffic should be as close as possible to the passenger station; if there are several passenger stations, these installations should be at the auxiliary stations, in the immediate neighbourhood of the receiving office;

5° The short-distance traffic and the long-distance traffic should be kept separate at all those stations where there is a considerable amount of short-distance traffic; the best way of doing this is to provide special sets of tracks, and if this is not possible, to provide individual tracks for the short-distance traffic. In the latter case, it is advisable to have the tracks for

Fig. 43. — Hungarian State Railway. — Goods shed at Fiume.

the short-distance trains next to platforms connected at right angles by a central platform;

6° It is also useful to place loops behind the passenger or auxiliary stations, so that the local trains which have arrived can be made ready to start again in the opposite direction in the shortest time possible;

7° The sorting station should be placed as far as possible between the main running lines, so that the trains running between the passenger station and the sorting station do not have to cross these lines. If overbridges or underbridges are however used, other arrangements can also be conveniently adopted;

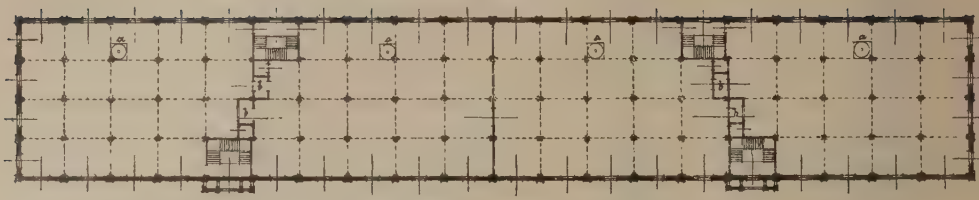
8° The changing of locomotives, at terminus stations, by means of turntables and traversers, is to avoided; switches are perferable, but the loop arrangement mentioned above is better still. At through stations separate readily-accessible tracks should be kept clear for changing the locomotives. The locomotive sheds should be as near to the station as possible, and where there is a sorting station, they should be in close connexion with the latter;

9° The addition and the removal of vehicles is best effected by means of dead-ended sidings located at the ends of the platforms. The marshalling of the trains, and the cleaning and the equipment of the carriages are best effected near the departure side, while trains can also be stored near the arrival side;

10° It is incontestably advantageous, in large towns, to have stations with the tracks above or below street-level. At such stations, the ticket offices, the offices for receiving and delivering luggage, the book and other stalls and the staff rooms should be on the ground floor, while the waiting and refreshment rooms and offices should be at track level;

11° At stations which are at street-level, hand trucks suffice for dealing with the luggage, while hydraulic or electric lifts seem desirable

General plan of 2nd and 3rd floor.



a = Sack shoot. — *b* = Lift. — *c* = Office.

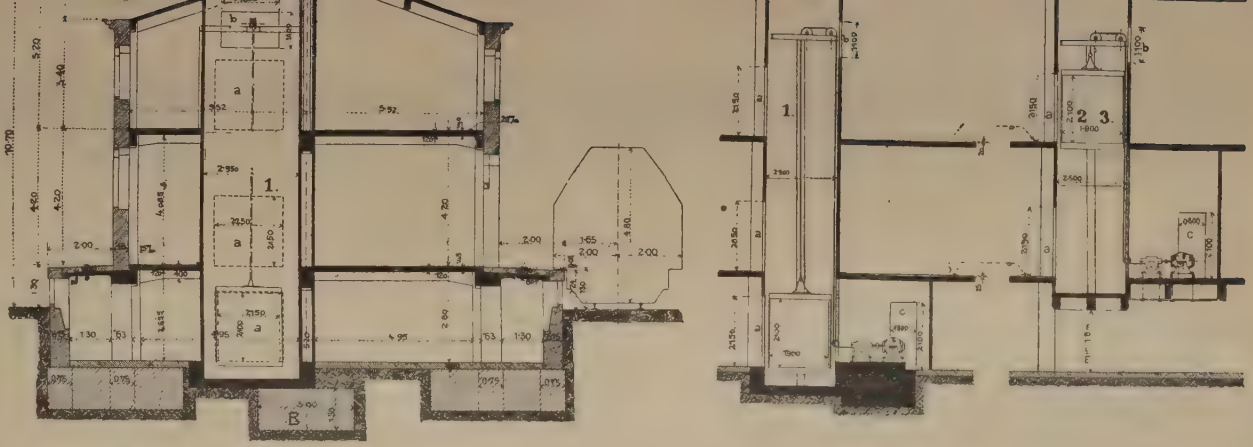
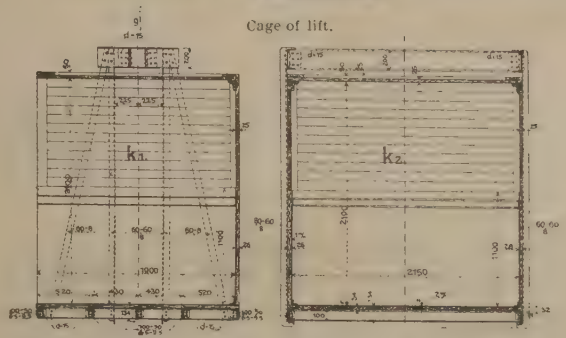
for raising and lowering the luggage at stations with several floors. The passengers should be given access to the island platforms by means of wide subways and convenient staircases, and if possible a separate subway should be provided as way out. If there is very much traffic, it is also advisable to have separate " way in " subways, for passengers of the first and second classes, and for passengers of the third class;

12° The goods yard can be built in an outer part of the town, but not too far from the commercial and industrial centres; it should be connected, by a suitable number of tracks, with the sorting and shunting yard which should be located in its neighbourhood;



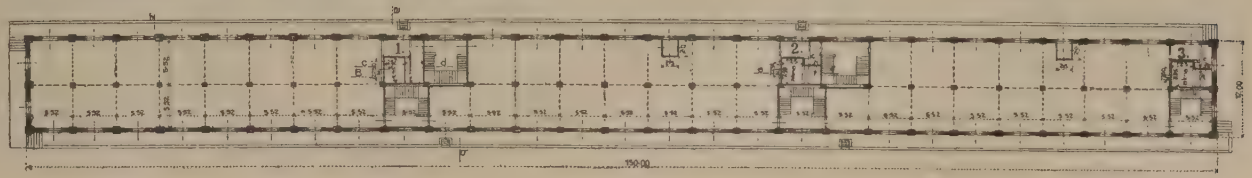
Cage of lift.



Inside dimensions of cage

Length	= 2·15 metres (7 ft. 5/8 in.
Width	= 1·90 metres (6 ft. 2 13/16 in.).
Height	= 2·10 metres (6 ft. 10 11/16 in.).

Side facing sea.



Plan of ground-floor.

Side facing tracks

Fig. 45.— Hungarian State Railway. — Electric lifts of goods shed No. III*a* at Fiume.
To carry 1,500 kilograms (3,300 lb.)

13° The sorting and shunting yard should be on a continuous incline, if the ground has a suitable slope for this purpose; if not, the use of saddle-backs will suffice. In order that the wagons should have continuity of movement during the shunting operations, the reception, the sorting, the marshalling and the departure sidings, should follow each other in regular order; moreover it is advisable to locate the whole sorting and shunting yard on both sides of the running lines in such a way, that the sorting for each direction is wholly carried out on the one side;

14° If the whole shunting and sorting yard is only on one side of the lines, the entrance and departure tracks should be as far as possible be placed above or below the running lines, so as to avoid the crossing of the latter;

15° Special sets of sidings for geographical sorting are advisable, if the number of wagons which have to be arranged according to station is considerable;

16° Moving wagons can be conveniently stopped by means of rail brakes and skids;

17° In single-floor goods sheds, wall slewing cranes and travelling cranes as well as capstans will suffice, while in the case of buildings with several floors, portal cranes and lifts can also be used with advantage.

SECTIONAL DISCUSSION

Meeting held on 5 July 1910 (morning).

MR. DIETLER, IN THE CHAIR.

The President. (In French.) — I call upon Mr. Jaggard, reporter for America, to explain the conclusions of his report.

Mr. Jaggard, *reporter.* — My report is divided into three parts : *a*) arrangements at the stations, measures taken for improving the service and increasing the safety, stations with separate floors in order to utilize the space in large towns better; *b*) arrangements for obtaining continuity of movement in shunting operations; *c*) baggage service, subways.

The conclusions I draw from my paper are as follows :

A. — Special arrangements calculated to increase the capacity of stations and safety of operation have been adopted in accordance with the needs of the different sections of the country. In some instances needs for fifty years ahead have been anticipated. The principle of separation of the various classes of traffic is observed to have application everywhere. In the older stations the separation of through from suburban traffic and the handling of baggage, mail and express in such manner as not to delay train movement and station operation is only accomplished by great ingenuity and the use of various make-shifts. On the other hand, the newer stations show most complete arrangements for radical separation and individual development of the various functions. In doing this, the loop is shown in only a few cases, but its more extensive use is indicated.

Excellent arrangements have been made and adequate facilities provided for all varieties of station work, including the cleaning and inspection of coaches, the making up of trains, their rapid movement into the stations, changing locomotives and coaches. Safety has been secured by the installation of proper interlocking, signal lay-outs and by a separation of lines and grades. Distinct progress and development in all of these features has been shown since the seventh meeting of the International Railway Congress in Washington.

A number of stations have been built in which the tracks are on different levels. The tendency is shown toward the adoption of this type of station. The offices are distributed between the floors according to space and utility. The adoption of separate floors has resulted,

*

from the requirements in large cities that grade crossings be eliminated, as well as by typographical conditions, value of real estate and other considerations. The more obvious advantages which result are: the consultation of public taste and comfort; more compact working, and in some instances a relative economy in operation.

Comparatively little has been done in the way of the adoption of new arrangements of platforms taking the country over. The same may be said of the adoption of new types of passenger cars, especially adapted for quick unloading.

The appliances for the conveyance of luggage show a development from the two-wheel and four-wheel truck to the electric automobile. Horizontal moving platforms are also contemplated.

For the conveyance of passengers progress is shown in the adoption to a limited extent of moving stairways. Electric and hydraulic elevators, however, are the devices usually found.

B. — All the recent designs show that effort is made to secure continuity of movement through the various yards. Heavy expenditures are made to attain this result. Without securing it by one means or another, it would be impossible to handle the traffic. The general method in vogue is to pass the cars over a hump standing between the receiving and classification yards. In well-designed yards nine-tenths of the cars pass through from one end to the other without a reversal of their movement. Exceptions are due to local conditions. Distant departure yards are used in the modern yards. The typical American yard group as now developed consists, therefore, of a receiving, a classification and a departure yard connected by humps or by natural grades, such a group being provided for movement in each direction. In a few of the larger yards the number of cars handled in twenty-four hours is as high as ten thousand.

The arrangement for handling cripple cars is usually to assign a track or tracks in the classification yard to which they run from the hump. Speaking generally, the relatively small volume of preference freight, high-class freight and local freight to be handled has not as yet necessitated separate facilities, but these classes of freight are usually passed along with the mineral and coarse freight over the same hump, the high-class freight being then handled on specially assigned tracks in the classification yard or in small pocket yards. Probably a more distinct separation will be brought about in the next few years, due to a variety of causes, among which are the necessity of moving high-class freight at nearly passenger speed and, therefore, on passenger tracks, the increased volume of high-class traffic, the separation of slow freight routes from passenger and high-class freight routes, the necessity for feeding and handling stock, icing perishable commodities, inspection, and diversion privilege.

To stop and start the cars, hand-brakes are depended upon. A few yards show derailing switches to stop run-away cars. Skids and other devices are used in exceptional cases.

C. — The appliances in common use are the two-wheel and four-wheel trucks; also special trucks for pianos, safes and heavy articles.

For high capacity trucks, fixed jib cranes and overhead cranes of various types are used. In storage warehouses horizontal conveyors are coming into use, as well as overhead travelling cranes.

A number of special devices designed to effect a distinct improvement in the quickness and cheapness of handling package freight have been considered. Many different arrangements have been worked out on paper but little practical result has been attained. The future is thought to hold many undeveloped possibilities in this line. The most radical step so far taken is the handling of package freight in the Chicago system of underground tunnels.

With the building of larger freight stations many improvements in design and arrangement of space have been accomplished. The subject is receiving much closer attention on the part of railways than obtained in former years.

The President. (In French.) — I call upon Mr. Jullien, reporter for all countries except America, Russia, Austria, Hungary, Rumania, Bulgaria, Servia and Turkey.

Mr. Jullien, *reporter.* (In French.) — Question IX, large stations, includes two separate parts :

The first, littera *A*, concerns large passenger stations ;

The second, littera *B*, concerns large goods stations.

My colleague, Mr. Leverve, will deal with this second part.

Littera *A* of the question is worded as follows :

Best arrangement of tracks, so as to increase their working capacity and ensure safety in shunting operations. Improved mechanical appliances for the conveyance of luggage, etc.

We drew up a detailed list of questions about this subject and sent it to the railway administrations concerned; we received thirty-three answers from the following countries :

South Africa, Germany, England, Australia, Belgium, India, France, Holland and Switzerland.

As was to be expected, the stations of which we received plans and about which we received information show great differences. On examining them however, one finds that in such large stations there is a tendency to adopt certain general principles which we will now enumerate :

The different tracks are as a rule not specially devoted to the reception or the dispatch of trains running in a given direction. In this way, the working capacity of installations of equal magnitude is increased. This common use of the trains is made possible by having large scissors crossings at each end of the station, connecting all the different tracks. In order to increase the working capacity of such stations still further, power signalling and switching arrangements are being used more and more instead of apparatus operated by hand, the power being supplied either by water under pressure, or by compressed air, or by electricity. Such power installations make it possible to operate the apparatus more quickly, and make it easier for the signalman, who no longer has to use his strength, to concentrate his attention on the operations which have to be carried out.

There is, however, a tendency to keep the suburban tracks separate from the main-line tracks, particularly when those suburban tracks can be placed at a different level from the main-lines; thus it is proposed to do this in Paris, at Saint-Lazare station.

This differentiation between the suburban services and the main-line services originates from a wider principle, which seems to be being adopted more generally, and which consists in keeping separate, as far as possible, the passenger service, and the parcels service, the mail service and the local slow-freight service. Thus all the space available is reserved for the passenger station proper, which is generally located in places where the purchase of land, in order to enlarge the station, is a very difficult and costly matter.

Acting from the same point of view, the marshalling sidings and the locomotive sheds are being removed more and more from passenger stations. These marshalling sidings as well as the sheds are then connected, as far as possible, with the station tracks by means of a double track used only for the shunting operations of locomotives or of sets of carriages used for making up trains.

At large stations, level crossings across the tracks, for use by the passengers, are generally avoided. As a rule, sub-ways are constructed for the purpose, except in the case of a terminus station where the different platforms are directly accessible from the main cross platform. It is for this reason often advisable, whenever local conditions make it possible, to have a station with floors, that is to say to place the passenger tracks either above or below the level of the station entrance and the booking office. In this way, the passengers are saved a useless ascent or descent. This arrangement also makes it possible to cross the streets of a town either above or below. Finally, this scheme generally makes it possible to effect important economies in the purchase of land. It is true that it becomes necessary to instal mechanical devices for lifting or lowering the luggage the height corresponding to the difference of level between the public roads and the railway. Electric or hydraulic lifts are very generally used for this purpose. These, like all appliances with reciprocating movements, have the disadvantage of giving only an intermittent and consequently rather limited output. This disadvantage does not make itself felt so much in the case of departing luggage, which arrives at the station at different times, so that enough time is available for dealing with it. But the same does not apply to arriving luggage, which comes all by the same train and nevertheless should be quickly delivered to the passengers. At several stations this has led, for instance at Paris (Quai d'Orsay and Invalides stations) and at Hamburg, to the installation of endless belts, which give a much quicker service. We will say several words about this point, when we deal with mechanical appliances.

What I have just said about stations with different floors cannot be applied without reservation to the English stations, where the luggage service is quite different from what it is in the other countries of Europe, and where it is recognized that cabs, etc., must have access to the arrival platforms, so that passengers after leaving the train can at once take them without going out of the

station. In such cases, a station with floors may lose part of its advantages.

Finally, I will say a few words about the mechanical appliances used for the conveyance of passengers, luggage and parcels.

Lifts are too well known to make it of interest to mention them.

The conveyance of luggage by travelling endless belts, such as have been installed by the Orleans Railway at Quai d'Orsay station, is however worthy of some mention. Horizontal belts, placed below the main-line arrival platforms, receive the luggage through openings arranged in the platforms, and take it to inclined belts, which raise it to the first floor and tilt it on to a sorting table. The following rule has been adopted for arranging the luggage on the delivery tables. Above the tables are placards shoving the figures 0, 1, 2, ... 9. All the packages the registered number of which ends with the same figure are placed on the table below the placard bearing that figure; and as the registered number is given on the luggage ticket which the passenger received when he registered his luggage, he knows at once, by looking at his luggage ticket, where he has to look for his luggage. The packages as they arrive at the sorting table are there taken by porters who direct it to the right or to the left, according to the last figure of the registration number. The packages thus arrive on a movable table which carries them horizontally in front of the receiving table. In the space between the movable table and the receiving table there are porters, at each placard, who remove the luggage corresponding to a given figure and place it below the placard bearing that figure. The packages, as soon as they have been identified by the passengers, are then placed on the delivery tables, at their disposition. In order to facilitate the handling, the delivery table is a little lower than the sorting table, and this is again a little lower than the movable table.

When this system is adopted the delivery of the luggage is effected very much more quickly than with the ordinary system of loading the luggage on to a truck, running it to the delivery tables, and unloading it there. One may say that the time required for the operation only depends on the quickness with which the luggage can be unloaded from the van on to the platform.

Similarly, at the Quai d'Orsay station the time required for the passengers to leave the station has been materially reduced by placing at their disposal a moving staircase. This staircase may be considered as formed by an endless chain going roud two drums, the one at the top being the driving drum, and the other being at the bottom. The links of this chain are formed by the steps which are separated by empty spaces of a width equal to that of the steps. The two upper and lower landing-places are formed by a kind of comb, through which the steps can pass during their movement of rotation.

The rate of movement of the passengers has been more than doubled by the use of this moving staircase.

Finally, I will conclude this summary by a short description of the mechanical sorting of the parcels at Paris-Austerlitz station. This sorting is only carried out as regards the parcels dispatched from that station, amounting on the average to

30,000 per day, of which about 20,000 are sent grouped, either as complete van loads to large stations, or packed into baskets, either to the stations of sufficient importance or to groups of smaller stations. The number of baskets dispatched each day from Paris-Austerlitz station averages about 900.

Nearly all the parcels use the evening train and are handed in by the consignors between 6 and 8 p. m.

The parcels, according to their labels, are marked with chalk, with one of the figures 0, 1, 2, 3 or 4, and are thrown into one of the openings in the platforms.

The figures 1, 2, 3 and 4 are used for the baskets only, and the figure 0 for full van loads.

An endless belt takes the parcels belonging to the first class side of the basket service, to a sorting table, where, in accordance with the figure marked on them, they are transferred by sorting porters to the belt corresponding to the figure with which they are marked. They are thus taken to a store-room bearing the corresponding figure. A first sorting operation by direction is thus effected.

When the time has come for getting ready a train corresponding to a given direction, the store-room in question is opened and the parcels contained in it are placed on to an endless belt passing along the bottom of it. The parcels are thus taken to a second sorting table, where there are seven inclined shoots to the reception tables.

Employees well acquainted with the railway system are placed at the sorting table for directing the parcels into the corresponding shoot; others are placed at the reception tables. The latter place them into the baskets corresponding to the different stations or different groups of stations of the section.

The packages which are marked with the figure 0 and are hence intended for full van-loads, only go through one sorting operation. They are directed into special store-rooms, six in number, each corresponding to one large station on the railway system. There they are placed into six special shoots and pass into the vans, under the action of gravity.

I have now completed the summary of that part of our report which refers to the passenger service, and I have the honour of proposing the following conclusions:

The preceding information leads us to conclude, as regards large passenger stations that in order to obtain the maximum working capacity, combined with safety of working, it is advisable in the first place to divert from them everything connected with the local goods and parcels services. It is equally advisable to concentrate the suburban service on certain tracks which are in principle reserved for it; but to utilize at certain hours or on certain days, where one of the two traffics, suburban or main line, becomes of preponderating importance, either the main lines for the suburban service, or the suburban lines for the main-line service. The establishment of large scissors crossings at the entrance of stations which makes it possible to receive a train coming from any direction on any of the tracks tends to become general and seems to be an excellent means for increasing the working capacity. The use of power-operated signals and switches, which can be set easily and quickly, and the use of which tends to become general, makes it possible to utilize these connections under the best conditions. It is, finally, an advantage to have in front of the different platforms tracks making it possible to change locomotives

quickly or to alter composition of trains quickly. A set of marshalling sidings near the station, and connected with it by independent tracks, is also a very useful addition to the installation.

When the local conditions allow it, it is as a rule of advantage to adopt either the type of a station with floors, or the type of mixed station, that is to say including tracks at two different levels. The ground is then utilized better, the passengers can be more easily distributed among the various platforms, and the luggage service can be carried out with much less inconvenience to the passengers.

The use of mechanical appliances for handling the luggage is much to be recommended, and, at stations with floors, the use of elevators to save the public the mounting of stairs, appears to be an important improvement, particularly when those elevators are of the continuous-action type.

It has to be added that it is rather exceptional to have to build a whole new large passenger station. It is much more usual to have to modify or enlarge an existing station; one is then hindered by local difficulties from applying the principles we have expounded, except to a limited extent. (*Applause.*)

The President. (In French.) — I now call on Mr. Leverve, the second French reporter on question IX.

Mr. Leverve, *reporter.* (In French.) — The second part of the question relating to large stations was worded as follows :

Large goods stations :

1° *Arrangements of tracks :* a) *to allow the continuity of movement of vehicles which require shunting and which are separate from the time the train bringing them has arrived until the train taking them away is being made up ;* b) *to prevent such movement from being interfered with by the arrival or departure of trains ;* c) *to stop without shock such separate vehicles at the end of the successive movements required ;* d) *to start them off again.*

2° *New appliances for handling goods.*

As the installations of goods yards depend on the requirements of the public, the nature of the local traffic and the topographical conditions resulting from their position in the towns, these yards naturally show great variety. It is hence hardly possible to draw any general conclusions as to how the sidings are arranged.

The same is not the case with sorting yards, which are yards used purely by the railway and to which the public has no access; these yards are used solely for making up and taking apart goods trains and for transhipping goods. Such yards can accordingly be constructed, and now frequently are constructed, in the open country and designed to suit as far as possible the corresponding traffic.

The plans and the information we have received from the different railway administrations in answer to our list of questions relating to their sorting and shunting yards, show that these yards show a general arrangement of which I will give a brief summary, mentioning the principles which seem to be involved.

In sorting and shunting yards of recent construction, attempts have been made to ensure the continuity of the movement of the cars which have to be dealt with, from the time an arriving train is received until a train is made up and ready to leave, so as to avoid any useless movements involving loss of time and extra shunting operations.

With this object in view, the sidings are as a rule arranged in three large sets over which the wagons which are being sorted pass from their entry into the station to their egress :

The reception sidings on which the trains to be sorted are received immediately on arrival, in order to await sorting operations. The number of these sidings depends on the number of trains which have to be received during the maximum length of that period of waiting. From all these sidings, the trains pass to a central set of sidings used for sorting;

The central set of sidings includes a number of sidings varying with the number and the importance of the lines terminating at the yard and of the sorting which has to be effected;

Finally, there are the departure sidings where the made-up trains wait till they have to start.

Moreover, the geographical classification of trains formed of several sections and in particular of pick-up goods trains can be effected either on a special set of sidings, similar to the others, but of much shorter length, or on one or more gridirons placed between the main sorting sidings and the departure sidings.

At many yards however these supplementary sidings or gridirons do not exist and the main set of sorting sidings is used itself for making up the trains, the geographical classification being effected on the ends of the sidings near the departure sidings, one or two lateral hauling lines being added to the departure set. In such cases the main sorting sidings as such receive a rather greater length.

The solution to be adopted from this point of view must evidently vary with the importance of the sorting yards and with the amount of geographical classification which has to be carried out, and also with the greater or lesser difficulties which may arise, in consequence of local conditions, in the construction of the sets of sidings.

At large sorting yards particular care is taken that the reception of the trains at the reception sidings and their dispatch at the departure sidings as well as the different movements of the locomotives should either not interrupt, or interrupt as little as possible the operations of sorting and of making up the trains. It is evidently of economic interest to carry out the work quickly as this involves both a reduction in working expenses as well as a reduction in the time during which the goods and the rolling stock are staying at the station. With this object in view, extra lines are laid passing round the other sidings and many junctions are made between the tracks of the latter, so as to make all the movements as independent as possible of each other.

The arrangements described exist in a more or less complete form at most of the large sorting yards about which we have received information, especially in France at Lumes (near Mézières), Saint-Pierre-des-Corps (Tours), Juvisy; and in Germany at Mannheim, Nuremberg and Dresden.

But it is important not to forget that to carry them out in full is a very expensive matter; such sorting yards become very large. Thus Lumes covers 50 hectares (123·5 acres), Nuremberg 100 hectares (247 acres) and Mannheim more than 200 hectares (494 acres); the installations must accordingly be more or less of a size

suited to the importance of the sorting operations which have to be carried out. An installation which would be justifiable at a station where the sorting operations are of considerable importance, would if adopted at a station of less importance involve an excessive capital outlay and even, if not proportioned to the work to be done, excessive working expenses for a service which would still be defective on account of its slowness.

The wagons are moved on the different sidings by being pushed up on to a saddle-back, or by having the tracks arranged on a continuous incline from one end of the yard to the other.

In the former system, which is that generally adopted in France, and it seems also in the other countries, except England, the set of sorting sidings is commanded on the reception side by a saddle-back on to which the trains to be sorted are pushed. It may even be advantageous to have two saddle-backs, side by side, at different levels, utilized according to the atmospheric conditions which may exist. The descent of wagons on sorting sidings is often hampered by the influence of wind and of frost.

The sorting sidings are on the flat or on a gentle down-gradient in order to facilitate the descent and the coupling up of the sorted wagons.

When there is no special set for the geographical classification, the main sorting sidings which are used for this purpose also, must have another saddle-back at their other end.

The set of sidings for the geographical classification is as a rule also furnished with a saddle-back, less high than that of the sorting sidings.

The arrangement of sidings on a continuous incline exists at some English yards, for instance at Edge Hill, also at yards on the French Northern Railway and at certain German yards, for instance Nuremberg, Dresden, etc.

It seems to be more suitable for quick operations owing to their simplicity and their constant direction from one end of the yard to the other, and it has the advantage of a considerable reduction in the cost of shunting operations of locomotives, which results in a considerable saving in working expenses. But this system is not very realizable in practice unless topographical conditions are specially favourable, and that is no doubt rather an exception.

The wagons are stopped, without shock, at the end of their different movements, either by means of their own brakes in the countries like England, where most of the wagons are equipped with hand brakes, or by means of skids, now very extensively used.

The latter, when well applied by the employee in charge, make it possible to stop, without shock, the wagon at a short distance from the others it is to join; it then moves this short distance down the gentle incline after the skid has been removed.

The rail-brake (*Gleisbremse*) is rather extensively used in Germany. It is placed a little below the top of the saddle-back and its travel is limited by a special device which throws the rail-brake off while the wagon it has checked continues its journey. It makes it possible to regulate the movement of the wagons, which is influenced by their load and by the existing atmospheric conditions.

The action of this rail-brake accordingly facilitates the work, but its use involves extra labour to start with, and is only possible when the saddle-back and the head of the sidings are sufficiently far apart.

The mechanical handling of wagons and of goods at the yards is becoming progressively developed.

The use of electric capstans and cranes for wagons is tending to replace manual labour and operations which take longer and cost more to carry out by means of horses or even engines. Certain stations have lines at different levels. The wagons are for instance loaded at a place which is at the same level as the adjoining streets, and then raised by lifts to another level, where the trains are made up.

In order to handle heavy goods in the yards or inside covered premises, hand cranes or electric cranes are used, as well as travelling cranes. These appliances have made it possible to have warehouses on different floors, such as are now found at certain stations, notably on those of the Orleans Railway, at Paris-Ivry and at Bordeaux, and also at a number of English stations. It is to be noted that in order to facilitate the mechanical handling of goods, English covered wagons are made with a top to open.

This special device does not exist in France.

At dock stations steam, hydraulic and electric cranes have for a long time been in use for transferring goods from a ship to a wagon or vice versa.

In this connection, it seems to us of interest to give a short description of the proposed installation at Bordeaux, on the right bank of the Garonne, for transferring coal, phosphates and minerals between the port and the Bastide station, which belongs to the Orleans Railway.

The operations of unloading these goods and taking them to the station are at present carried out as follows : the empty wagons are taken by a locomotive from the station to tracks parallel to the dock. They are then taken by hand, by means of turntables, to small tracks laid fanwise near the piers. There they are loaded up by means of steam cranes taking the coal out of the vessels laying alongside. The loaded wagons are then taken back to the station by a similar series of operations conducted in an inverse order.

In the proposed scheme, two landing-piers for ships will be used for the traffic in question. Each of them will be equipped with four electric cranes, together capable of unloading about 200 tons per hour, which by means of good grabs will take the coal out of the ships alongside the piers and discharge it into a vast hopper.

An electric suspended railway built along the pier, 1,200 metres (1,312 yards) in length, will convey the coal from that hopper to the place where the wagons are loaded, which adjoins the station. This railway will be double and its upper part will include rope hauling cages capable of conveying 200 tons per hour. The cages will become filled as they pass the hopper, and will convey the coal in a continuous manner to the loading place in the station. The hopper will act as a regulating device, so as to equalize temporary variations in the outputs of the unloading cranes and the suspended railway.

On arrival at the loading place, the

cages will be unlocked automatically and discharge their contents into motor hoppers, moving parallel to the suspended railway, above two rows of wagons, so as to fill all of them in succession.

Moreover, a coal store will be established at the loading place in order to receive the fuel intended for the company's use. It will be equipped with a travelling crane making it possible to take the coal to the store and take it up again by means of grabs in order to load it automatically into wagons.

As I have already stated, the suspended railway will be double, the upper part being used for the cable operating the conveyance to the station, as already explained, and the lower part being equipped with automatic electric cages for taking coal to several industrial establishments, which will be connected up with the system.

The installation described will be able to deal with a considerable tonnage, and will effect a very material saving by substituting powerful electric cranes for the old steam cranes and by eliminating the use of wagons and the laborious operations in connection with them. Finally, the quick rate of unloading will result in a much better utilization of the landing-piers, to the advantage both of commerce and of local navigation.

I may add that these installations are justified by the importance of the tonnage of the goods in question : namely more than 1,200,000 tons of total traffic on the piers on the right bank of the Garonne, more than one third of which is fuel supplied to the Orleans Railway.

After these explanations, gentlemen, you will allow me to repeat to you the conclusions which we have the honour of proposing to you in our report :

Shunting yards can as a rule be built in the open country and constructed to suit the purpose they are intended for, without having their design influenced by local conditions foreign to the working conditions of lines which are to be provided for.

Such yards, it seems, should in all cases include three sets of sidings for : the standing after the entry, for the sorting and finally for the marshalling and standing before the start, of the trains to be dealt with. The length of those sidings depends on the length of the trains, and their number, on the density of the traffic.

When the yards have to provide for a very busy traffic, other sidings of less importance are added for the geographical sorting.

Finally, these can all be doubled, so as to have two distinct complete sets, one for the one direction and the other for the other.

It is a great advantage to arrange these different sets as well as the running lines, in such a way as to obtain a continuity of movement in the shunting operations and to eliminate any interruption of these operations owing to the arrival or departure of trains.

Shunting yards cannot practically be built with a continuous incline unless the ground has a natural slope; and in most cases it appears preferable to have saddle-backs. The skid seems to be the best appliance for stopping wagons.

The mechanical handling of the goods or wagons in the buildings and near the buildings, by means of hand cranes or electric cranes, of electric capstans, of lifts, etc., tends to become developed and constitutes an important improvement. It results in the more frequent use of buildings with several floors. (*Applause.*)

The President. (In French.)— The fourth reporter, Mr. Kain, has unfortunately died

and we can only express our regrets at the death of this eminent man. (*Approval.*)

Mr. Kramer, who was to replace him, is detained at the 1st section and will not be able to be here before 2 o'clock. As however Mr. Kain's report and his conclusions are in our hands, I think there is no disadvantage in continuing the discussion. (*Approval.*)

I therefore propose to you to begin the general discussion at once. This will not prevent us from making any alterations if Mr. Kramer brings forward new ideas and suggestions. We, moreover, start from the principle that the first conclusions which we draw up are not to be considered as final.

You seem to agree that our discussion should take as basis the conclusions given in Messrs. Jullien and Leverve's report. That will of course not prevent us from taking the other opinions also into consideration.

You will find these conclusions in the two last pages of their report; the following is the first clause :

" The preceding information leads us to conclude, as regards large passenger stations, that in order to obtain the maximum working capacity, combined with safety of working, it is advisable in the first place to divert from them everything connected with the local goods and parcels services."

Mr. Weiss, *vice-president.* (In French.) — That conclusion seems to me to be too absolute.

The statement is : " It is advisable in the first place to divert from them everything connected with the local goods and parcels services."

There is no objection in accepting this wording as regards goods, but the same does not apply to parcels; those are often conveyed by special trains, but frequently also by passenger trains. Under these conditions it is not possible to keep the parcels service and the passenger service entirely separate. We ought to say : " and, as far as possible, everything connected with the parcels service ".

Parcels must be handled near the passenger platforms.

Mr. Jullien. (In French.) — We quite agree with Mr. Weiss's proposal.

The President. (In French.) — Then there is no difference between Mr. Jullien's opinion and that of Mr. Weiss.

Mr. Jaggard, *reporter.* — Does this conclusion mean that the baggage service shall be entirely apart and independent from the passenger service, or in the same station, but with entirely distinct arrangements? To give an example, I will cite the new station of the Pennsylvania Railroad, at New York : the baggage is handled upon the same general station level as the passengers, but on the arrival of the trains at the platforms the baggage is handled by special means in such a manner as to cause little or no interference with the movement of passengers; the baggage is conveyed by elevators to the proper floor, and thence is trucked to the baggage room, without interfering with the other station operations. I wish to know whether the conclusion takes account, in its wording, of an arrangement of this kind, which seems to me to be very well worked out.

Mr. Jullien. (In French.) — It is a

question of settling a wording which will satisfy everybody. We did not take the American system into consideration, but it seems that the parcels service and the passenger service are distinct and separate in some cases, but not in others.

Mr. Weiss. (In French.) — Are these installations, for lowering parcels to the subways, at the same place at which passengers get out or at a place specially used for this service?

Mr. Eckenstein, *secretary-reporter.* — The conclusion in the report for America does not mean exactly the same thing as that given in Messrs. Jullien and Leverve's report.

Mr. Jullien. (In French.) — In order to come to a general agreement, one might say :

" As regards large passenger stations, it is advisable, in order to obtain the maximum working capacity, combined with safety of working, to divert from them everything connected with the local goods service. It is also advisable to keep separate, as far as possible, the installations used for the passenger service and those used for the parcels service."

— Adopted.

The President. (In French.) — We pass to the second conclusion :

" It is also advisable to concentrate the suburban service on tracks which are in principle reserved for it; but to utilize at certain hours or on certain days, when one of the two traffics, suburban or main line, becomes of preponderating importance, either the main lines for the suburban service, or the suburban lines for the main-line service."

— Adopted.

" The establisment of large scissors crossings at the entrance of stations, which makes it possible to receive a train coming from any direction on any of the tracks, tends to become general and seems to be an excellent means for increasing the working capacity. The use of power-operated signals and switches, which can be set easily and quickly, and the use of which tends to become general, makes it possible to utilize these connections under the best conditions. It is, finally, an advantage to have, in front of the different platforms, tracks making it possible to change locomotives quickly or to alter the composition of trains quickly. A set of marshalling sidings near the station, and connected with it by independent tracks, is also a very useful addition to the installation."

— Adopted.

" When the local conditions allow it, it is as a rule of advantage to adopt either the type of a station with floors, or the type of mixed station, that is to say including tracks at two different levels. The ground is then utilized better, the passengers can be more easily distributed among the various platforms, and the luggage service can be carried out with much less inconvenience to the passengers."

Mr. Bagwell, Midland Railway, England. — I shall be glad if the reporter will tell as whether he considers the arrangement of floors at different levels to be as advan-

tageous in the case of through stations as in the case of terminal ones.

Mr. Leverve. (In French.) — The stations with different floors have perhaps greater advantages, as regards the movement of the passengers and the handling of the luggage, in the case of through stations than in that of terminus stations. In the latter case, the operations can be carried out on the cross platform at the end of the tracks; but this is not possible in the case of through stations. But it may also be observed that terminus stations are generally inside large towns, where stations with floors may also present considerable advantages.

Mr. Bagwell. — The answer satisfies me.

The President. (In German.) — Would it not be advisable to make a small alteration in the conclusion so as to draw a distinction between through stations and terminus stations?

Mr. Weiss. (In French.) — I propose that we should say :

" When the local conditions allow it, it is often of advantage to adopt, etc."

Mr. Bagwell. — I support that.

— The conclusion as amended is adopted.

The President. (In French.) — " The use of mechanical appliances for handling the luggage is much to be recommended, and, at stations with floors, the use of elevators to save the public the mounting of stairs, appears to be an important improvement, particularly when those elevators are of the continuous-action type."

Mr. Jaggard. — Where movable staircases and like devices are used, what arrangement is there for taking care of invalids or children? In large stations it frequently happens that as many as 50 such passengers a day would have to move between levels. Is it not necessary to install elevators for the handling of these people? If so, is not the double arrangement much more expensive than providing elevators only?

Mr. Jullien. (In French.) — I think that it is useful to place employees by the mechanical appliances for facilitating the conveyance of the passengers. Where there is a difference of level, fixed staircases are always necessary, but the luggage lifts can be used, exceptionally, for invalids. The two arrangements should always exist side by side.

Mr. Jaggard. — That is entirely satisfactory.

The President. (In French.) — In exceptional cases, it is advisable to take exceptional measures. Should the conclusion not be modified to this effect?

Mr. Jullien. (In French.) — We do not propose to abolish the fixed staircase where a moving staircase exists. The public must have the choice between the two.

The President. (In French.) — Taking the observations which have been made into consideration, I now put the conclusion to the vote.

— Adopted.

" It has to be added that it is rather exceptional to have to build a whole new large passenger station. It is much more

usual to have to modify or enlarge an existing station ; one is then hindered by local difficulties from applying the principles we have expounded, except to a limited extent."

I think it useful to remark that lately whole stations have been entirely rebuilt, and that several stations have been replaced by one single one. Now it is only when it is a question of a new station that it will be possible to apply the principles which have just been enunciated.

It is in that sense, I think, that the conclusions are to be understood.

— Adopted.

We now pass to the conclusions relating to large goods yards, the first clause of which is as follows :

" Shunting yards can as a rule be built in the open country and constructed to suit the purpose they are intended for, without having their design influenced by local conditions foreign to the working conditions of lines which are to be provided for."

Mr. Kareischa, *principal secretary*. (In French.) — The wording of this clause seems to me to be too absolute. As local conditions can change, the wording should be slightly modified and run : " Shunting yards can, as a rule, be built in the open country and constructed to suit the purpose they are intended for, without having their design less influenced thant hat of passenger stations by local conditions foreign to the working conditions of lines which are to provided for."

Mr. Ulbricht, *vice-president*. (In German.) — I propose simply to say second sentence : " Their design is less influenced by ..."

Mr. Leverve. (In French.) — We could divide the clause and say : " Shunting yards can as a rule be built in the open country and constructed to suit the purpose they are intended for. Their design is in fact less influenced than passenger stations by local conditions foreign to the working conditions of lines which are to be provided for."

Messrs. Kareischa and Ulbricht. (In French.) — We agree.

— The first clause as amended by Mr. Leverve is adopted.

The President. (In French.) — We now pass to the second clause.

" Such yards, it seeems, should in all cases include three sets of sidings for : the standing after the entry, for the sorting and, finally, for the marshalling and standing before the start, of the trains to be dealt with. The length of those sidings depends on the length of the trains, and their number, on the density of the traffic."

Mr. Kareischa. (In French.) — I propose to add at the end of that clause : " and the shunting operationes ".

Mr. Leverve. (In French.) — Exactly.

Mr. Petschkovsky, Russian State Railway. (In French.) — I find in this clause that the number of the sidings depends on the density of the traffic. But the number of the sidings depends also on the part played by the station in the group of stations of a given railway system, and there can be a busy traffic without that

station having to make up trains to be dispatched to great distances. Each large station plays a certain part in a group of other goods stations. It follows that stations must add other sidings, because the wagons for long-distance trains must often wait a certain time, sometimes more than twenty-four hours, sometimes even forty-eight hours.

Hence it should be stated that the number of sidings depends on the density of the traffic and on the part played by the station in the group of stations of a given railway system.

Mr. Leverve. (In French.) — Mr. Petschkovsky's remark is true. That sentence in our conclusions is too absolute.

Evidently the number of sidings does not depend only on the density of the traffic, as a yard catering for coal pits and having to send off much coal can have much traffic and very few sorting sidings.

It should be stated that the number of the sidings is affected by the different conditions existing on each system.

We consider the set of reception sidings on which the trains are received on arrival and from which the wagons are then sent, either by means of a saddle-back or by means of a continuous incline, to the sorting sidings proper. The number of sidings of this set must be large enough to be able to hold all the trains which may arrive before the wagons are shunted.

As regards the set of sorting sidings proper, the number of sidings necessary depends on the number of lines which run into the yard and on the conditions which obtain. If a yard must make a special classification for fifteen different stations, then there must be fifteen sidings available. If it has to serve ten differen directions, and if there are three destinations on each of these lines, thirty sidings would be required in order to make complete sorting possible.

Then there is what we call the geographical classification which is effected by means of gridirons.

One might perhaps say in the conclusion : " The number of sidings is determined by the number of lines which have to be served and by the importance of those lines."

Mr. Kareischa. (In French.) — And by the importance of the classes of trains.

Mr. Leverve. (In French.) — If a line is important, we give it two, three tracks.

Mr. Descubes, French Eastern Railway. (In French.) — Certain lines can be divided into several sections. Hence one should say : " lines or sections of lines ".

Mr. Jullien. (In French.) — While I agree with the remarks which have just been made, it seems to me impossible to consider all these details. I accordingly propose the following wording : " The length of the siding depends on the length of the trains, and their number, on the density of the traffic and the number of directions which have to be served ".

Mr. Jaggard. — This portion of the conclusions shows distinctly the difference which exists between yard plans in Europe and in America. We find further on this phrase : " We can then double the facilities and made two distinct groups, one for each direction ". This seems to indicate that it is intended to utilize the three consecutive yards in the same direction as

long as the traffic is not too heavy; then when the movement becomes large, to establish separate yards for the handling of the traffic in the different directions. Take the case of a yard lying from west to east, and comprising three groups: The first group is a reception yard; the second is a classification yard, and the third is a departure yard. With a series of yards so arranged, the trains that come from the west are conveniently handled in accordance with the plan. If, on the other hand, a train comes from the east, it is necessary that it should pass by the entire group and be handled from the west end; as a result a useless detour is made.

In America, such an installation would have a length of two or three miles; consequently, the trains which arrived from the wrong direction would make a useless journey of five or six miles. This does not seem to me to be advantageous, and it can scarcely be the purpose of the reporters to recommend the employment of one group of yards only. It would seem preferable to so dispose the initial outlay as to allow a better handling of a small traffic, but to so plan the yards as to permit of an expansion later on into two separate systems, each composed of three yards, one being for each direction.

I read later in the report of Messrs. Jullien and Leverve:

> With the arrangement on a continuous slope, we are obliged to concentrate all the assorting movements in the same direction for cars coming into a station from all directions. The receiving tracks for all directions are grouped at one extremity, A, the departure tracks at the other extremity, B, and all the cars are sent in the direction A to B.

This seems to confirm my impression that unnecessary movement is contemplated.

A little further on, the same reporters say:

> In hump yards one can, when the importance of the traffic justifies it, as at Mannheim, arrange side by side two series of tracks, where are assorted simultaneously in opposite directions the cars which arrive at the two opposite extremities of the yard.

I should like to advocate that it is certainly desirable for us to help the science of railroading by making progress. We ought to be careful about approving in conclusions things that are perhaps done now, but which we know are not the best that can be done. We ought to state that in theory the best plan consists in anticipating an independent arrangement in each direction. As in the case of the stage coach, one uses and is content with this method of travel if he has no better way of travelling, but he hopes to get that soon.

To cite an example, I would mention the classification yards at Altoona: A few years ago the classification of the west-bound empty and loaded movement was accomplished by an arrangement which involved reverse movement, but there resulted such difficulties that a very great expense was incurred to better the arrangement. Then the hump yard system for west-bound classification was established, and now there is a complete group of separate sorting yards for each of the two directions. It will be seen by some figures how important the movement in this yard is: The average number of cars switched daily at Altoona in the busier months is about 10,000. The weight of

*

a large proportion of the cars is about 70 tons. The reconstruction of the yard cost about $3,000,000.

I think it would be better to say that the best solution consists in always anticipating two groups of classification yards, suited to the two directions, but in the beginning to avoid a complete arrangement in one direction only, by adopting a plan which will allow, even at the start, facilities for classification in two directions, so arranged, as to be capable of being expanded into two complete systems.

The President. (In French.) — Mr. Jaggard's remarks bear on the following two clauses :

" When the yards have to provide for a very busy traffic, other sidings of less importance are added for the geographical sorting.

" Finally, these can all be doubled, so as to have two distinct complete sets, one for the one direction and the other for the other."

I think that Mr. Jaggard aims chiefly at the last sentence and that he would place at the head of the conclusions the general principles concerning the modification or multiplication of certain arrangements at stations.

Mr. Leverve. (In French.) — The conditions considered by Mr. Jaggard are peculiar to a few large yards where 10,000 wagons have to be dealt with per day. I think that yards of this importance do not exist in Europe, and even in America they must be very rare. Our report applies, it is true, to large yards, but not to exceptional yards of which perhaps only three or four exist in the whole world.

Meeting held on 5 July 1910 (afternoon).

The President. (In French.) — I call upon Mr. Jaggard.

Mr. Jaggard, *reporter.* — I beg leave to state :

" Yards ought to have ordinarily three groups of tracks, for a receiving yard near the entrance, a classification yard, and a departure yard. The length of the tracks depends upon the length of the trains, and their number depends upon the density of traffic and other circumstances that may arise."

When a yard is to accommodate a very extensive traffic, one has to add to these yard groups others of less importance to allow geographical classification; if the traffic is not sufficiently important to render necessary the two arrangements cited above, one for each direction, it is expedient to form provisional plans in order to avoid reverse movements; as far as possible they should be planned in a way to permit later growth, in the manner above indicated.

It is considered that reverse movements are wrong in principle, and that they bring difficulties of operation which should be avoided.

Mr. Leverve, *reporter.* (In French.) — In my opinion, there is something lacking

in the conclusion proposed by Mr. Jaggard. It states at the end that it is advisable to make provision for future duplication for wagons in each direction. Now at the beginning, there is no question of this desideratum and Mr. Jaggard limits himself to repeating the terms of our conclusions.

In order to make the final part of the proposal agree with the initial part, a slight modification should be introduced, and we should speak of the system for each direction.

Mr. Reverdin, *secretary-reporter*. (In French.) — Mr. Leverve will be satisfied if the phrase in question is preceded by the following sentence : " Finally, these can be doubled, so as to have two distinct sets, one for the one direction, another for the other."

The President. (In French.) — That would then only be an addition.

Mr. Reverdin. (In French.) — This is the proposal :

" Such yards, it seems, should in all cases include three sets of sidings for the standing after entry, for the sorting and, finally, for the marshalling and standing before the start, of the trains to be dealt with. The length of these sidings depends on the length of the trains, and their number, on the density of the traffic.

" Where the station has to deal with a very busy traffic, to these sidings other sidings of less importance are added for the geographical sorting. Finally, they can be doubled so as to have two distinct sets, one for the one direction and the other for the other."

Here would come the new wording proposed by Mr. Jaggard :

" When the traffic is not important enough to make the above-described arrangements necessary, it is advisable to make provisional installations making it possible to avoid movements in opposite directions.

" These installations should be designed, as far as possible, with a view to future enlargements. It must be recognized that movement in opposite directions is wrong in principle ; it increases the cost of working and makes it more difficult."

Mr. Serani, Italian State Railway. (In Italian.) — Sorting yards must satisfy the double condition of making it possible to make up trains for the same destination and trains for the different stations on one and the same line.

The very examples given by Messrs. Leverve and Jullien lead to the deduction.

In fact at Mannheim and at Nuremberg yards, which have 153 and 110 kilometres (95·32 and 68·35 miles) of track respectively, as well as at Lumes yard which has only 53 kilometres (32·93 miles) of track, there are not only three sets of sidings for reception, for sorting by direction and for departure, but there are also one or more sets of sidings for making up trains for the successive stations on one and the same line.

Hence at large sorting yards it must be possible, with wagons coming various ways, not only to make up trains for given directions, running to given stations, but it must also be easy to make up trains intended to serve all the stations on one and the same line.

Mr. Jullien, *reporter*. (In French.) — The

difference of opinion between Mr. Jaggard and ourselves is above all due to the fact that we are not considering the same subject. The American reporter considers large stations to be those where 10,000 wagons are dealt with per day. In our opinion it would be excessive to have such a complete installation at the yards which we have considered, yards where only 3,000 to 4,000 wagons are dealt with per day.

In order to come to a general agreement, we propose to modify the fourth clause of our conclusions as follows :

" Finally, one can double them so as to form two distinct complete sets, one for the one direction, the other for the other. "

" It is very desirable to do this in the case of a station of very great importance, where the traffic justifies the expense. It is advisable to design the installations in such a way as to admit of future increase of traffic."

Mr. Maresch, Rumanian State Railway. (In French.) — The expression " one for the one, the other for the other " might give rise to confusion.

It would be better to say " two distinct sets for the two directions ". Moreover, these sets should be connected, for in Germany the wagons coming from the north go to the south and *vice versa*. It is then necessary to have easy ways for passing from the 1st set to the 2nd and *vice versa*.

Mr. Leverve. (In French.) — Mr. Jaggard laid much stress this morning on the importance of sorting in the one direction the wagons arriving at the one end, and of sorting those arriving at the other end in the opposite direction, so that no wagon need make any double journey.

In our conclusions we used the terms " the one direction and the other " without attaching any geographical meaning to them.

There is one first system including three sets of sidings for trains coming from the one side, and a second system for those coming from the other. But it is quite certain that for one given line there will be wagons arriving from the south and wagons arriving from the north. If we call the lines on the north side 1, 2 and 3, and the lines on the south side 4, 5 and 6, we can have wagons coming on line 1 which are intended for line 2 and which consequently must leave on the same side as that on which they arrived. Hence, it is not possible to avoid having wagons making a double journey. There are many cross lines, and wagons coming from the east, for instance, may be divided between the north and south lines.

It is hence impossible to avoid cases of double journeys.

That being so, I think that the wording proposed by Mr. Jullien should be satisfactory to everybody.

Mr. Jullien. (In French.) — This is the new wording which we have the honour to propose.

" Finally, they can be doubled so as to have two distinct complete sets for the two chief directions which have to be provided for, connecting them so as to make it possible to pass from one to the other. It is very desirable to do this in the case of a station of very great importance, where the traffic justifies the expense. It is advisable to design the installations in such a way as to admit of future increase of traffic."

Mr. Kareischa. (In French.) — We should say : " two distinct systems " instead of " two distinct sets ". (*Approval.*)

Mr. Maresch. (In French.) — It is also necessary to add " with convenient connections between the two systems ". This is essential in the case of important yards.

Mr. Jullien. (In French.) — The next paragraph meets this points. It runs : " It is a great advantage to arrange these different sets, as well as the running lines, in such a way as to obtain a continuity of movement in the shunting operations and to eliminate any interruption of these operations owing to the arrival or departure of trains."

Mr. Maresch. (In French.) — In the large yards in Germany, there are two systems which are nearly independent of each other.

Mr. Jullien. (In French.) — In order to pass from one line to the other, the wagons must be sorted.

Mr. Maresch. (In French.) — In order to pass from the northern system to the southern system, the wagons use the connecting lines.

The President. (In French.) — The following is the fourth clause proposed by Mr. Jullien :

" Finally, these can all be doubled so as to have two distinct complete sets, for the two chief directions, connecting them so as to make it possible to pass from one to the other. It is very desirable to do this in the case of a station of very great importance, where the traffic justifies the expense. It is advisable to design the installations in such a way as to admit of future increase of traffic."

— Adopted.

The President. (In French.) — Would it not be advisable to reconsider the second clause ?

It was said this morning that the number of the sidings does not exclusively depend on the number of the trains.

Mr. Jullien. (In French.) — The following wording has been agreed to :

" The number of the sidings depends on the density of the traffic as well as on the number of directions which have to be served."

Mr. Kareischa. (In French.) — I should like to have the idea expressed that the number of sidings depends on the sorting system adopted.

Mr. Jullien. (In French.) — It depends on the nature of the traffic and not on the nature of the goods.

Mr. Leverve. (In French.) — We might say : " The number of the sidings depends on the density and on the subdivision of the traffic, that is to say, on the number of lines ending at the station and on the subdivision of the traffic."

We may assume that at all stations of a certain importance there is a saddle-back or an incline.

Mr. Kareischa. (In French.) — Sorting with a saddle-back nearly always takes twice as long as sorting with an incline.

As for the time of standing still, it depends on the set of sidings.

Mr. Jullien. (In French.) — That is so if we consider the set of reception sidings.

But that is not the case with the set of sorting sidings proper. It is difficult to express this idea in two lines.

Mr. Kareischa. (In French.) — If you say that the number of sidings does not depend on the density of the traffic, the question is not solved.

Mr. Jullien. (In French.) — I propose to say :

" The length of these sidings depends on the length of the trains, and their number on various conditions, more especially on the density and the nature of the traffic, on the method of sorting and on the number of directions which have to be served.

" When the yard has to provide for a very busy traffic, other sidings of less importance are added for the geographical sorting."

Mr. Serani. (In French.) — I propose to word the second clause as follows :

" Such yards, it seems, should in all cases include three sets of sidings for : the standing after the entry, for the sorting and, finally, for the marshalling and standing before the start, of the trains to be dealt with."

— Adopted.

Mr. Leverve. (In French.) — For the next sentence, I propose the following :

" The length of the siding depends on the length of the trains, and their number, on the density of the traffic and the number of directions which have to be served. "

— Adopted.

The President. (In French.) — We pass to the third clause. Mr. Serani proposes the following :

" At very large stations, where a very busy traffic has to be provided for, other sidings of less importance are added for the geographical sorting."

— Adopted.

The President. (In French.) — We pass to the fifth clause :

" It is a great advantage to arrange these different sets, as well as the running lines, in such a way as to obtain a continuity of movement in the shunting operations and to eliminate any interruption of these operations owing to the arrival or departure of trains."

Mr. Maresch. (In French.) — I propose to add to the end of this clause : " or to the movement of engines."

— The clause as amended is adopted.

The President. (In French.) — We pass to the sixth clause :

" Shunting yards cannot practically be built with a continuous incline unless the ground has a natural slope; and in most cases it appears preferable to have saddle-backs. The skid seems to be the best appliance for stopping wagons."

Mr. von Rybicki, Austrian State Railway. (In German.) — I will ask the meeting whether the results of existing experience are such as to make it possible to assert this as definitely as asserted in the conclusions. In my opinion, there are different points in favour both of the one and of the other system. In the first place one has to consider the cost of construction, then the number of shunting engines

required, which is of less importance than with the other systems, and, finally, the climatic conditions and the number of wagons damaged. Certain of those factors are beyond doubt in favour of the continuous incline. I therefore repeat my question : Is there really enough experience to justify that saddle-backs should be recommended in such cases?

Mr. Ulbricht. (In German.) — I absolutely agree with the opinion expressed by Mr. von Rybicki. I also cannot admit that a continuous incline is only to be preferred if the ground has the necessary slope. From the financial point of view, that theory would no doubt be correct in many cases. But there are also many cases where a continuous incline can very well be constructed on level ground. I am just thinking of a case which exists on the Saxon State Railway, and where, as I have just stated, the configuration of the ground was not the preponderating factor. It can also not be definitely said, from the point of view of working, that the saddle-back is absolutely superior. According to the experience gained on the Saxon State Railway, sorting operations on a continuous incline are carried out under such satisfactory conditions that it is hardly possible to assert in a general way that a saddle-back is superior.

Mr. Leverve. (In French.) — The answers we have received seem to show that the continuous-incline method is to be preferred because the sorting is effected more quickly. I must however record that in the case of large stations, the system more frequently adopted is that of a saddle-back. It accordingly seems that railway administrations prefer the saddle-back system to the continuous-incline system.

Mr. Weiss. (In French.) — The first sentence of that clause of the conclusions is too absolute. We should modify it and say : " When the ground has a natural slope, sorting yards with continuous inclines are to be preferred. " In that case, the last words should be struck out : " and in most cases it appears preferable to have saddle-backs ".

Mr. von Rybicki. (In German.) — I think there is a misunderstanding. The choice of system depends on the financial questions. There are so many factors to consider that the configuration of the ground cannot be the sole criterium. I have to build a sorting yard on the railway which I manage, and with this object in view I sent a commission to Nuremberg, to Hesse, and to various other points. I collated the information collected and considered several schemes, but as yet I have not definitely decided whether I will adopt the saddle-back system or the continuous-incline system. Besides the cost of construction, one also has to consider future working expenses. I am hence of opinion that the question of the ground is a secondary one. The choice of system depends on the results given by the calculations, which depend on the number of the wagons, the climatic conditions, etc.; hence I doubt whether I can give any preference to either system in such a definite way.

Mr. Jaggard. — In America the hump has given very good results, and is generally considered the best system. Certain

yards have even been remodelled to introduce this feature.

Mr. Dantscher, Bavarian State Railway. (In German.) — The results obtained by the Bavarian State Railway at Nuremberg sorting yard which is on a continuous incline, are very satisfactory, and I do not think that we can express an absolute preference in favour of the saddle-back system. I am of opinion that in certain cases where the conditions are similar to those at Nuremberg, it is very suitable to construct sorting yards with continuous inclines, above all because the working expenses are materially lower. It is nevertheless possible, in the case of yards of exceptional size, that the saddle-back system may be superior taking the whole operation into consideration.

At Nuremberg very special conditions had to be allowed for. All the trains, both those coming from the north and the south and those coming from the east and the west, collect together at a reception station at the east end of the shunting yard, in order to be dealt with subsequently. Owing to the division into two groups, the traffic of the whole yard is sorted, on the one hand, for the directions north and west, on the other, for the directions south and east.

When the conditions are such that the different traffics balance each other, a continuous-incline installation can always be advantageous, above all when it is a question of a traffic of about 5,000 wagons per day. In the case of a very busy traffic, of say 8,000 to 10,000 wagons per day, the use of saddle-backs may be preferable, particularly if the different traffics balance each other less well than at Nuremberg.

I think that the two systems must be applied in accordance with the local conditions, and that neither the one nor the other is to be preferred absolutely.

Mr. Leverve. (In French.) — Taking into consideration the remarks which have been made, I propose to say :

" Shunting yards can be built either on a continuous incline, or with saddle-backs. The choice between the two systems has to be decided in each individual case, taking into consideration the nature of the traffic, the cost of construction, which varies with the local conditions, and the eventual operating expenses of each of the two systems."

The President. (In German.) — We will reconsider the question of this wording. In the first place I should like Mr. Watson to address the meeting.

Mr. H. A. Watson, North Eastern Railway, Great Britain. — During the last few years we have built three large sorting yards with saddle-backs, and we are so well satisfied with the results obtained that future sorting yards will be constructed on the same principles, the advantages being :

1° This system makes it possible to operate a greater number of wagons than formerly;

2° Goods are damaged much less ;

3° The whole of the sorting operations can be carried out very quickly.

In fact I fully agree with the opinion of the American delegates that an absolute preference should be given to saddle-backs.

The President. (In German.) — Would it not be advisable to add to the conclu-

sions that the English and Americans give the preference to saddle-backs?

We find ourselves face to face with two opinions which have the right of being expressed in the conclusion. In the wording submitted by the French reporters, it is said that the saddle-back is more often to be preferred. The second wording simply says that the two systems, saddle-back and continuous incline, are of equal value and that any choice between them depends absolutely on the conditions of each individual case.

I think that we must express an opinion as to these two solutions and say whether we will give absolute preference to the saddle-back or whether we let the choice depend on the local conditions. It will hardly be necessary to discuss the details of the wording, but simply to say which of the two systems is to be preferred ; the second wording has only been proposed as a result of the various objections raised.

As the reporters inform us, there are also in England and in America many yards with continuous inclines. Hence, it is necessary that I should reopen the discussion of these questions of principle.

Mr. Ulbricht. (In German.) — It is not possible to take into account the opinion of a certain number of delegates by adding to the wording proposed by the reporters (and I think well of this text), a sentence stating that exceptionally satisfactory results have been obtained with saddle-backs on rather a large number of railways? (*Hear, hear !*)

Mr. Petschkovsky. (In French.) — Is from the purely technical point of view a sorting yard with a continuous incliue always preferable?

Mr. Descubes. (In French.) — I think that the saddle-back is often preferable from the technical point of view. If at certain stations it is a question, for instance, of dividing a train of 60 wagons into a number of smaller sections, of 10 and 15 wagons each, the continous-incline system may have advantages. But matters are different if the train is to be divided into 30 sections of from 1 to 3 wagons each. It is in fact important that these sections should clear as quickly as possible the switches which have to be operated. Consequently the steeper the gradient at the start and at the switches, the more quickly the latter will be cleared and the greater the output of work.

In this case, which is much more usual than the other, the saddle-back with a steep gradient is to be preferred.

Mr. Leverve. (In French.) — The words used in our concluaions are a little absolute and perhaps we go rather far in saying that " shunting yards cannot practically be built with a continuous incline unless the ground has a natural slope ".

There are cases where this condition does not exist and where the continuous-incline system may still be superior. Such is, for instance, the case mentioned by Mr. Descubes when important numbers of wagons moving together have to be operated.

It would hence be better to retain the wording which I just proposed.

Mr. Eckenstein, *secretary-reporter.* — The American delegates agree to this wording.

The President. (In French.) — As everybody agrees, I declare it adopted.

We now pass to the next sentence :

" The skid seems to be the best appliance for stopping wagons."

Mr. Jaggard. — The skid is not used in America or England. Experience has demonstrated that in America heavy cars are jolted out of position on the tracks when the skid is used. It is possible that it is different in Europe ; but as our conclusions interest the entire world, I propose that we modify the conclusion and say that hand-brakes under good conditions of inspection seem the best way to stop the cars in America and in England. The skid is preferred by the Continental railways.

Mr. H. A. Watson. — I agree with Mr. Jaggard. On our railway, we have made trials which have shown that heavy wagons weighing 30 tons are not safely stopped except by means of the hand brake. On the other hand, light wagons are easily stopped by means of a skid. The selection of the one or the other system will accordingly depend on the type of wagon.

Mr. Leverve. (In French.) — Mr. Jaggard's wording appears to me to be satisfactory. It shows that the system adopted in America and in England differs from that adopted on the Continent. He knows better how things stand in this respect than we do.

I also think that the choice between the two systems is affected by the nature of the rolling stock. It is possible that in America, where large wagons are used, the skid tends to derail these vehicles. On the other hand, the necessity of having an employee on each wagon in order to apply the brake is less objectionable in the case of large wagons than in that of small.

Mr. Ulbricht. (In German.) — Would it not be advisable to say : " The best appliance for stopping light wagons and wagons of medium weight appears to be the skid." In the case of very heavy wagons, we ourselves have found that the sudden stopping produced by the skid can easily produce damage. If we adopt this limitation, we at the same time meet the wishes of the Americans, and they will no doubt be able to agree to this.

Mr. Eckenstein, *secretary-reporter.* — The American and English delegates agree to this wording.

The President. (In French.) — The conclusion will accordingly run as follows :

" The skid seems to be best appliance for stopping light wagons."

— Adopted.

The President. (In French.) — We still have to consider the last clause :

" The mechanical handling of the goods or wagons in the buildings and near the buildings, by means of hand cranes or electric cranes, or electric capstans, of lifts, etc., tends to become developed and constitutes an important improvement. It results in the more frequent use of buildings with several floors."

— Adopted.

I now call upon Mr. Kramer to give a summary of the third report, that of Mr. Kain, relating to the same question.

Mr. Kramer, Hungarian State Railway. (In French.) — I beg to thank the President for the kind words he has spoken in memory of my late colleague Mr. Kain, words which the meeting has fully endorsed. I also thank him for kindly asking me to give a summary of his report.

That being said, I think I may limit myself to adding that the conclusions provisionally adopted by the section are in agreement with those given in Mr. Kain's report. I hence entirely agree and propose that they should be definitely adopted.

The President. (In German.) — Does the section agree with Mr. Kramer that the provisional conclusions should be adopted?

Many delegates. — Yes, yes!

— The conclusions provisionally adopted were then put to the meeting and adopted definitely.

DISCUSSION AT THE GENERAL MEETING

Meeting held on 14 July 1910 (afternoon).

MR. P. WEISSENBACH, PRESIDENT, IN THE CHAIR.

GENERAL SECRETARY : MR. L. WEISSENBRUCH.

FIRST ASSISTANT GENERAL SECRETARY : MR. MÜRSET.

SECOND ASSISTANT GENERAL SECRETARY : DR. A. BONZON.

Mr. Kareischa, *principal secretary of the 3rd section*, read the

Report of the 3rd section.

(See *Journal de la huitième session*, No. 8, p. 3.)

" Mr. JAGGARD gave a summary of his report which was divided into three parts: *a*) arrangements at the stations, measures taken for improving the service and increasing the safety, stations with separate floors in order to utilize the space in large towns better; *b*) arrangements for obtaining continuity of movement in shunting operations; *c*) baggage service, subways.

" Mr. JULLIEN gave a summary of his report as far as passenger stations were concerned. In order to utilize existing tracks as much as possible, it was advisable to keep the suburban passenger service and the main-line service separate. Subways added to the safety of the passengers. At stations with separate floors, lifts and continuous-action systems of conveyance were being used. The parcels service could also be facilitated in similar ways.

" Mr. LEVERVE spoke about goods yards. Sorting operations were carried out by means of three sets of sidings. The length of these sidings depended on the number of wagons dealt with. The movement of the wagons was started by means of locomotives or by gravity. Such sorting sidings could be either on a continuous incline, or with saddle-backs. The wagons were stopped by means of skids. The reporter concluded with some information about the mechanical handling of goods."

LITTERA *A*.

" As regarded keeping the passenger and the parcels services separate, Mr. WEISS (*French Eastern Railway*) remarked that parcels had to be dealt with near the passenger platforms.

" Mr. JAGGARD stated that in America the

parcels were unloaded on the side of the passenger platform, but were taken away through subways.

" Mr. Bagwell (*Midland Railway*) asked, in connection with stations with separate floors, whether these were considered advantageous both in the case of terminus stations and in that of through stations.

" Mr. Leverve remarked that local conditions were the chief factors in the case of terminus stations with several floors, while in the case of through stations this system was best from the point of view of safety.

" Mr. Jaggard remarked that the use of some of the mechanical means of conveyance for passengers gave rise to some difficulty in the case of inexperienced people and of invalids.

" Mr. Jullien answered that the fixed staircases were always necessary and that the luggage lifts could be used for invalids in exceptional cases."

Littera *B*.

" Mr. Kareischa (*Russian government*) proposed to begin the conclusions referring to the goods yards by the following paragraph : " Shunting yards can as a rule be built in the open country and constructed to suit the purpose they are intended for. Their design is, in fact, less influenced than that of passenger stations by local conditions foreign to the working conditions of the lines to be provided for."

" As regarded the conditions determining the number of tracks, Messrs. Kareischa, Petschkovsky (*Russian State Railway*) and Jullien were of opinion that it was also necessary to consider the number of directions to be provided for.

" Mr. Jaggard was of opinion that at large yards, as at Altoona, it was indispensable to have two groups of three sets each, so as to provide for the two opposite directions. This also made subsequent extension easier.

" Mr. Leverve remarked that this conclusion in his opinion only applied to stations of ordinary importance, but not to exceptional and rare cases.

" Mr. Serani (*Italian State Railway*) thought that it was in all cases necessary to have one set of sidings for the geographical sorting.

" Mr. Maresch (*Rumanian State Railway*) suggested an alteration in the wording so as to make the meaning more clear.

" Messrs. Jullien and Maresch thereupon proposed a new wording in the conclusions. As regarded the sidings, it was decided to add " or to the movement of engines " after the words " arrival or departure of trains ".

" A discussion then took place on the relative advantages of saddle-backs or humps, and of continuous inclines, which showed that the former were preferred in America and in England, while on the Continent local conditions formed the chief factor in deciding the question.

" Messrs. Jaggard and H. A. Watson (*North Eastern Railway, England*) preferred saddle-backs. Mr. Dantscher (*Bavarian State Railway*) was more in favour of the continuous incline, but local conditions had to be taken into account.

" Mr. von Rybicki (*Austrian State Railway*) thought that it was not possible to give the preference, in an absolute manner, to either system.

" Mr. Ulbricht (*Saxon State Railway*) said that the practical possibility of having a continuous incline did not merely depend on the natural slope of the ground; such an incline could also be made by utilizing the spoil from earth-works.

" Mr. Descubes (*French Eastern Railway*) described the advantages of saddle-backs when a set of wagons had to be divided into a large number of separate parts; the greater speed of the wagons at starting made it possible to clear the sidings more quickly and to get through more work.

" Mr. Leverve proposed the following wording, which was accepted : " Shunting yards can be built either on a continuous incline, or with saddle-backs. The choice between the two systems has to be decided in each individual case, taking into consideration the nature of the traffic, the cost of construction, which varies with the local conditions, and the eventual operating expenses of each of the two systems."

" The use of the skid was objected to by Messrs. Jaggard and H. A. Watson, who stated that in America and England this had produced derailments in the case of heavier wagons (30 tons and upwards).

" Mr. Ulbricht stated that on the German railways skids had also proved unsatisfactory for heavy wagons. He accordingly proposed a modification in the wording of the proposed conclusions.

" The report of Mr. Kain, who had died, was submitted to the section by Mr. Kramer (*Hungarian State Railway*). He in the first place thanked the meeting for the regrets expressed on the death of Mr. Kain.

" As the conclusions of his report were in general harmony with those that had been adopted, Mr. Kramer agreed with them *in toto*.

" Mr. Serani suggested another slight modification in the wording of the conclusions, which was accepted.

" The section then agreed to submit to the general meeting the conclusions worded as follows."

The President. (In French.) — The following are the

CONCLUSIONS.

Littera *A*.

" As regards large passenger stations, " it is advisable, in order to obtain the " maximum working capacity, combined " with safety of working, to divert from " them everything connected with the " local goods service.

" It is also advisable to keep separate, " as far as possible, the installations used " for the passenger service and those used " for the parcels service. It is also ad- " visable to concentrate the suburban ser- " vice on tracks which are in principle " reserved for it; but to utilize at certain " hours or on certain days, when one of " the two traffics, suburban or main line, " becomes of preponderating importance, " either the main lines for the suburban " service, or the suburban lines for the " main-line service. The establishment " of large scissors crossings at the en- " trance of stations, which makes it pos-

" sible to receive a train coming from any " direction on any of the tracks, tends to " become general and seems to be an " excellent means for increasing the " working capacity. The use of power- " operated signals and switches, which " can be set easily and quickly, and the " use of which tends to become general, " makes it possible to utilize these con- " nections under the best conditions. It " is finally an advantage to have, in front " of the different platforms, tracks mak- " ing it possible to change locomotives " quickly or to alter the composition of " trains quickly. A set of marshalling " sidings near the station, and connected " with it by independent tracks, is also a " very useful addition to the installation.

" When the local conditions allow it, it " is often of advantage to adopt, either the " type of a station with floors, or the type " of mixed station, that is to say includ- " ing tracks at two different levels. The " ground is then utilized better, the pas- " sengers can be more easily distributed " among the various platforms, and the " luggage service can be carried out with " much less inconvenience to the passen- " gers.

" The use of mechanical appliances for " handling the luggage is much to be re- " commended, and, at stations with floors, " the use of elevators to save the public " the mounting of stairs, appears to be an " important improvement, particularly " when those elevators are of the con- " tinuous-action type.

" It has to be added that it is rather ex- " ceptional to have to build a whole new " large passenger station. It is much " more usual to have to modify or enlarge " an existing station; one is then hin- " dered by local difficulties from applying " the principles we have expounded, ex- " cept to a limited extent."

LITTERA *B*.

" Shunting yards can as a rule be built " in the open country and constructed to " suit the purpose they are intended for. " Their design is in fact less influenced " than passenger stations by local con- " ditions foreign to the working condi- " tions of lines which are to be provided " for.

" Such yards, it seems, should in all " cases include three sets of sidings for : " the standing after the entry, for the " sorting and finally for the marshalling " and standing before the start, of the " trains to be dealt with. The length of " the siding depends on the length of the " trains, and their number, on the den- " sity of the traffic and the number of " directions which have to be served.

" At very large stations, where a very " busy traffic has to be provided for, " other sidings of less importance are " added for the geographical sorting.

" Finally, these can all be doubled so as " to have two distinct complete sets, for " the two chief directions, connecting " them so as to make it possible to pass " from one to the other. It is very desir- " able to do this in the case of a station " of very great importance, where the " traffic justifies the expense. It is advis- " able to design the installations in such " a way as to admit of future increase of " traffic.

" It is a great advantage to arrange these " different sets, as well as the running " lines, in such a way as to obtain a con-

" tinuity of movement in the shunting " operations and to eliminate any inter- " ruption of these operations owing to " the arrival or departure of trains, or to " the movement of engines.

" Shunting yards can be built either on " a continuous incline, or with saddle- " backs. The choice between the two " systems has to be decided in each indi- " vidual case, taking into consideration " the nature of the traffic, the cost of con- " struction, which varies with the local " conditions, and the eventual operating " expenses of each of the two systems.

" The skid seems to be best appliance " for stopping light wagons.

" The mechanical handling of the goods " or wagons in the buildings and near " the buildings, by means of hand cranes " or electric cranes, or electric capstans, " of lifts, etc., tends to become deve- " loped and constitutes an important " improvement. It results in the more " frequent use of buildings with several " floors."

— These conclusions were adopted by the general meeting.

SECTION III : WORKING

[656 .257 & 656 .21 (01]

QUESTION X

OPERATION OF SWITCHES AND SIGNALS

A. *Improved centralized installations for operating switches and signals. The use of water, of compressed air, of electricity, for working the transmissions. Electric interlocking. Route levers.*

B. *Arrangements adopted to prevent switches taken from the facing or the trailing side from changing their position before the whole train has passed.*

C. *Use of diagrams to facilitate the consideration of the full utilization of tracks along passenger platforms and the modifications to be made, in cases of urgency, in the way these tracks are used.*

Reporters :

Holland. — Mr. L. H. N. Dufour, engineer to the Company for working the Netherlands State Railways.

Austria, Hungary, Bulgaria, Denmark, Germany, Luxemburg, Norway, Rumania, Russia, Servia, Sweden, Switzerland and Turkey. — Professor Dr. Ulbricht, member of the Board of works, councillor of the Royal Saxony Treasury.

America. — Mr. E. C. Carter, chief engineer, Chicago & North Western Railway.

Other Countries. — Mr. L. Weissenbruch, engineer in chief, director of the safety appliances department of the Belgian State Railways, and Mr. J. Verdeyen, engineer, assistant to the director of the safety appliances department of the Belgian State Railways.

REPORT N° 1

(Austria-Hungary, Bulgaria, Denmark, Germany, Luxemburg, Norway, Rumania, Russia, Servia, Sweden, Switzerland and Turkey)

By Prof. Dr. ULBRICHT,

MEMBER OF THE BOARD OF WORKS,

COUNCILLOR OF THE ROYAL SAXON TREASURY.

In order to obtain a good general view of the progress which is being made or attempted in connection with the safety appliances considered under Subject X, it was also necessary to incorporate in this report the chief particulars of the older devices principally used, which have proved reliable. The list of questions sent out therefore also included operation by hand, and to this the first twenty-eight questions are devoted. Power operation is then dealt with in the next nineteen questions, Nos. 29 to 47. Questions Nos. 48 to 65 deal with those devices which can be applied in cases both of hand operation and of power operation in order to obtain special safety measures, with the exception, however, of the electric interlocking of route levers, to which a special section, including questions Nos. 66 to 77, is devoted. Questions Nos. 78 to 94 deal with the measures taken to prevent the moving of switches, whether taken from the facing or from the trailing side, before the whole of the train has passed over them. The last nine questions, Nos. 95 to 103, are devoted to the graphic representation of the occupation of platform tracks at stations where there is much traffic, and to their utilization if any changes are made in the regular time-table.

*

Answers to the list of questions sent out were received from the following administrations :

I. — Members of the German « Verein ».

GERMANY.

Imperial Administration of the Alsace-Lorraine Railway, Strasburg.
Royal Prussian Central Railway Office (of the Prussian-Hessian State Railway), Berlin.
Royal Bavarian State Traffic Ministry; section Munich.
Royal Administration of the Saxon State Railway, Dresden.
Royal Administration of the Wurtemberg State Railway, Stuttgart.
Grand ducal Administration of the Baden State Raiway, Karlsruhe.
Administration of the Oldenburg State Railway, Oldenburg.

LUXEMBURG.

The Administration of the Prinz-Heinrich Railway, Luxemburg.

AUSTRIA AND HUNGARY.

Imperial and Royal Railway Ministry, Vienna.
Administration of the Royal Hungarion State Railway, Budapest.
General Management of the Austrian Southern Railway, Vienna.
Administration of the Austrian North-Western and North-South Railway, Vienna.
Administration of the Aussig-Teplitz Railway, Teplitz.
Administration of the Kaschau-Oderberg Railway, Budapest.

RUMANIA.

Administration of the Rumanian State Railway, Bucharest.

Addendum :

General Management of the Warsaw-Vienna Railway, see under Russia.

II. — Outside the German « Verein ».

DENMARK.

Administration of the Danish State Railway, Copenhagen.

RUSSIA.

Administration of the State Railway, St. Petersburg.
General Management of the Russian North-Western Railway, St. Petersburg.

District Management of the Moscow-Brest State Railway, Moscow.
District Management of the Ssysran-Wjasma State Railway, Kaluga.
District Management of the Weichsel lines, Warsaw.
General Management of the Warsaw-Vienna State Railway (belonging to the German *Verein*).
District Management of the South-Eastern Railway, Woronesh.
District Management of the Moscow-Windau Railway (Moscow-Windau-Rybinsk Railway Company), Moscow.

SWEDEN.

Royal Administration of the Swedish State Railway, Stockholm.

SWITZERLAND.

Administration of the Swiss Federal Railway, Berne.
General Management of the St. Gothard Railway, Lucerne.

In this list, which serves as basis for the further discussion, the Warsaw-Vienna line, although belonging to the German *Verein*, has been included, for the sake of convenience, in the second section, under the heading Russia.

As regards Luxemburg, in which the Prinz-Heinrich Railway is situated, no separate section has been formed; but the information supplied, which only refers to the first part of the questions, has been considered in its proper place. As regards the conditions on the Wilhelm-Luxemburg Railway, the information supplied in connection with the Imperial Alsace-Lorraine Railway applies equally, for that administration manages the Wilhelm-Luxemburg Railway.

As regards the practice on the Russian railways, the information given by the Administration of the State Railway (this controls 22 State lines and more than 10 company's lines) was our principal source of information, but the answers supplied by the managements of the Moscow-Brest, Ssysran-Wjasma, Weichsel and Warsaw-Vienna lines gave valuable supplementary information.

The answers sent by the Russian North-Western, and by the Russian South-Eastern, could not be dealt with in this report, as they were in the Russian language, which the Reporter is not acquainted with. Attempts to obtain them in German, or in French, were unsuccessful.

The Bulgarian State Railway refrained from answering the questions set, for as there is not yet much traffic on the lines of this administration, perfected centralized switching arrangements are not used; and as regards electric operation there is as yet only a small experimental apparatus at Slivnitza.

The managements of the Bukovinia Local Railway, of the Mohacs-Pecs Railway, of the Polessia State Railway, and of the Salonica-Constantinople and Smyrna-Cassaba lines gave similar reasons for their inability to supply the information

desired. The Polessia State Railway, however, drew attention to a special safety system introduced on their lines, known as the Phono-Indicator system.

In order to give a general view of the information collected, we give in the following table the chief items contained in the answers to the 103 questions, arranged under the different countries Germany, Austria-Hungary, Rumania, Denmark, Russia, Sweden and Switzerland. The verbatim reproduction of the answers is, for the sake of comprehensiveness, not attempted. But it was considered important to show what conditions are the prevailing ones in the country in question. In connection herewith it is to be noted that some of the answers were very brief, and that consequently it is not always possible, from the information supplied, to determine the state of affairs as accurately as might be desirable. In the text which follows the tables, attempts are made to give some supplementary information, and to make it easier to obtain a general view of the subject.

Tabular summary of the answers.

QUESTIONS.	Summary of the answers.	
	Germany.	Austria and Hungary.
A. — I. Improved appliances for operating switches and signals. Use of water, compressed air and electricity as sources of power.		
1-28 : *Hand operation.* (The work of moving the signal or switch is done by the signalman.)		
1. When you are newly constructing switching gear, do you use rodding or double-wire transmissions, or both? In which cases do you use the one, in which the other, system of transmission?	Double-wire transmissions are used very extensively for the operation of switches, rodding only exceptionally in the case of short transmissions and minor signal cabins. In Baden and Alsace-Lorraine alone is rodding to be used exclusively in the future for new installations, as double-wire transmissions are considered not to be reliable enough, in case of fracture of a wire.	In the case of new constructions, ble-wire transmissions exclusivel
2. What length of travel of the rodding, or of the wire, do you as a rule use in such transmissions?	In the case of older installations without point lock up to the lower limit of 140 millimetres (5 1/2 inches), rodding; in the newer installations usually 220-240 millimetres (8 11/16 to 9 7/16 inches), rodding; and 500 millimetres (1 ft. 7 11/16 in.), wire. In Bavaria 600 millimetres (1 ft. 11 5/8 in.), and in some cases even 750 millimetres (2 ft. 5 1/2 in.), of travel of wire are used.	As a rule : 500 millimetres (1 ft. 7 11/16 travel of wire, exceptionally 600 millimetres (1 ft. 11 5/8 in.). Austrian Southern goes beyond t up to 680 millimetres (2 ft. 2 3/4 in. the distance between the switch the signal cabin exceeds 250 me (273 yards).
3. Are the switches operated by rodding equipped with separate locking gear, operated from the cabin, and in what cases?	Yes. In Prussia and Alsace-Lorraine as a principle, if passenger trains take the switches from the facing side. A similar system is also adopted in other cases, but only if the switches are at a considerable distance from the signal cabins, if indeed rodding is still used at such longer distances. (In Baden it is used at distances of over 300 metres (328 yards.)	Such locking gear as a rule does enter into consideration, as dou wire transmission is usual. Aussig-Teplitz Railway has such its more important switches wh are taken from the facing side.
4. Have you also used ball and roller bearings for any rotating parts of your switching gear, and with what success?	As a rule not. But trials have been made with ball bearings for semaphore arms and deviation blocks, and have given general satisfaction. In the case of signals not frequently used, it was observed in Alsace-Lorraine that the arms were less liable to become rusted in.	As a rule not. Trials have been m by the Aussig-Teplitz Railway w ball bearings at the supporting rol and deviation blocks, and have sho that friction is materially reduced
5. Are the switches operated by rodding equipped with any electric control, which if the switch is wrong (fracture of a rod, points not home) prevents the setting of the signal or at least enables the cabin to recognize the fault?	As a rule, no. But in Alsace-Lorraine in the case of installations with signals electrically and switches mechanically operated (rod transmissions) the point lock is controlled electrically. If the points are not home however, the signal coupling circuit in interrupted.	No.
6. Do you use, besides the usual cuttable point locks, which react on the cabin, any other devices intended to fulfil some similar function?	No.	Instead of cuttable point locks, react on the cabin, the switch bolt w shearable pin is used nearly exclu vely; this, although cuttable, does react on the cabin. Throwing o the lever after cutting is prevented locking the switch bolt. The Aus Teplitz Railway however also ext sively uses cuttable reacting po locks.

Summary of the answers.

Rumania.	Denmark.	Russia.	Sweden.	Switzerland.
A. — I. Improved appliances for operating switches and signals. Use of water, compressed air and electricity as sources of power.				
1-28 : *Hand operation.* (The work of moving the signal or switch is done by the signalman.)				
case of new construc- s, rodding almost ex- sively, and that on ount of the local wea- r conditions, as well on that of the relia- ty and cheapness of intenance of the rod- g installations.	In the case of new constructions, chiefly double-wire transmissions.	In the case of new constructions, double-wire transmissions are put in nearly exclusively. Only the Weichsel Railway uses rodding to some extent, and the Ssysran-Wjasma Railway uses it exclusively.	In the case of new constructions, double-wire transmission exclusively.	In the case of new constructions, just as in the existing ones, rodding is used almost exclusively. Only in exceptional cases, if the switches are a very long way off, or if it would be difficult to arrange rodding, or if it is a question of switches not taken from the trailing side, are double-wire transmissions, with special point lock, also used.
el of rodding, 236 milli- res (9 5/16 inches). el of wire, 500 milli- res (1 ft. 7 11/16 in.).	As a rule : travel of rodding, 230-250 millimetres (9 1/16 to 9 13/16 inches); travel of wire, 450-500 millimetres (1 ft. 5 11/16 in. to 1 ft. 7 11/16 in.).	Travel of rodding : 209·5 millimetres (8 1/4 inches), Ssysran-Wjasma Railway ; 260 millimetres (10 1/4 inches), Weichsel Railway. Travel of wire, 480-500 millimetres (1 ft. 6 15/16 in. to 1 ft. 7 11/16 in.).	As a rule : travel of wire, 500-520 millimetres (1 ft. 7 11/16 in. to 1 ft. 8 1/2 in.).	As a rule : travel of rodding, 236 and 240 millimetres (9 5/16 and 9 7/16 inches); travel of wire, 475 and 500 millimetres (1 ft. 6 11/16 in. and 1 ft. 7 11/16 in.). In new constructions : wire, 600 millimetres (1 ft. 11 6/8 in.).
but only exception- ly, if they are taken n the facing side and on a curve.	Yes, when the distance between the switch and the cabin exceeds 250 metres (273 yards).	No	Such locking gear does not enter into consideration, as double-wire transmission is usual.	Yes. On the Federal Railway, switches in the main lines, which are taken from the facing side, are specially locked by the wire transmission operating the signal, if they are more than 150 metres (164 yards) from the cabin. Switches with a rod travel of over 400 metres (437 yards) in addition have a special lock, which is operated from the cabin by a double-wire transmission.
	Yes, ball bearings have been used with satisfactory results for signal arms.	No.	No.	No.
only in the case of se operated by wire nsmission. In these es, an alarm rings if points are not home.	No.	As a rule, no.	This control does not come into consideration as double-wire transmissions are generally used.	No.
	No.	Yes, on the State Railway, Siemens & Halske switch-bolts without special point locks.	No.	No, some older installations excepted.

QUESTIONS.	Summary of the answers. (Continued.)	
	Germany.	Austria and Hungary.
7. Have you made any arrangements for preventing the untimely opening (when a route has been made) of the cuttable connexion between the switch lever and the transmission, or do you intend to make such arrangements?	Only in so far as the opening of the connection between the switch lever and the transmission cannot be effected without the breaking of a lead seal, and the special lever required for such opening is kept lead-sealed.	As a rule there is no reason for this switch bolts are used.
8. What construction of cuttable point locks do you prefer in the case of new installations, the locking by clamping the blade and the stock rail together, or by exerting a thrust against the blade from a special point of support, or by some other method?	The locking by clamping the blade and the stock rail is as a rule preferred more recently. Wurtemberg and Baden use the thrust method only.	In the case of the ordinary switch lo the blade is pressed against the st rail by a thrust exerted from a spe point of support. The locking clamping the blade and the stock together is only used at the loca operated switches of the Austr Southern Railway.
9. Have the usual arrangements, by means of which, if a wire breaks, the switch is held in its end position, and the setting of the signal is prevented, proved sufficiently satisfactory to justify the loss of simplicity in construction which consequently results?	Yes. But in some cases these locking arrangements are only considered necessary in the case of switches with long wire transmissions.	Such arrangements are as a rule no be found, as point locks are gener used here. Breakages of the tra mitters have only occurred v rarely. The Aussig-Teplitz Railw speaks in favour of such lock arrangements.
10. Do you under certain conditions have, in the case of switches operated by wire transmissions, even if supplied with point locks and with the arrangement described under 9, special locking gear (control bolts) operated from the cabin, and in what cases?	Yes, in the case of switches taken from the facing side by passenger trains running at higher speeds; also in the case of switches operated from greater distances (over 300 or 350 metres [328 or 383 yards]). In Alsace-Lorraine such special gear is provided in the case of all switches taken from the facing side by passenger trains.	Yes, nearly always in the case of sw ches taken from the facing side passenger trains, operated fron distance; occasionally also in the c of switches on branch lines, but o if the distance between the swi and the cabin exceeds 200 met (219 yards). On the Hungarian lin in the case of switches taken from facing side by express trains.
11. Do you think it advisable to check by means of such controlling locking gear the condition of the switch as a whole, or each blade separately?	The predominant opinion is that it is advisable to check the position of each separate blade. Checking the position of the switch as a whole has however also proved to be reliable. The latter system is preferred by Bavaria in the case of switches having locks of a very simple and reliable construction.	The checking of the position of switch as a whole is as a rule effec by the control bolts used. On Aussig-Teplitz Railway, when two points are moved in successi the position of each is checked.
12. To what extent do you use centralized locking only, instead of centralized operation of switches?	In most cases where simple conditions of traffic do not make frequent operation of the switches necessary; also in cases of greater distances, when it is difficult to see the switches; also when for special reasons an employee is required anyhow (for instance, for attending to gates). Bavaria uses locking as a preliminary safety measure and then limits it to switches taken by ordinary trains from the facing side, and to switches taken by through trains from the trailing side.	At branches in the open line, in orde prevent the premature throwing-o of switches while a train is passi Also at stations when the work conditions are simple and there is little traffic; also when the switc are at greater distances from cabin.

Summary of the answers. (Continued.)

Rumania.	Denmark.	Russia.	Sweden.	Switzerland.
	No.	As a rule, no.	No.	No.
ing by exerting a thrust m a special point of pport is preferred.	The Siemens & Halske or the Schnabel & Henning. (Thrust from a special point of support.)	Locking by exerting a thrust from a special point of support is as a rule preferred. The Warsaw-Vienna Railway pronounces in favour of locking by clamping.	Locking by exerting a thrust against the blade from a special point of support, because in consequence of the system of construction of the standard switches no other methods of locking can be used.	Locking by exerting a thrust against the blade from a special point of support.
	As yet there is not enough experience to make a definite answer possible.	Yes, quite satisfactory when trials of the breaking of wires were made; the breaking of a transmission has only occured very rarely.	As yet there is not enough general experience. On the Stockholm-Rimbo line these arrangements have proved satisfactory.	Yes. The St. Gothard Railway however is unable to decide the question as no case of fracture of a wire has yet occurred.
o the present such con- l bolts have not been ed.	Yes, at the switches which are regularly taken from the facing side, if the length of the wire transmission exceeds about 200 or 250 metres (219 or 273 yards).	Yes, in certain cases of switches in the main lines taken from the facing side; also in the case of entrance switches taken from the facing side, which are at a rather considerable distance from the cabin.	Yes, as a rule in the case of important switches taken from the facing side, particularly at stations at which fast trains do not stop.	Yes, as a rule in the case of switches in the main line taken from the facing side, if the trains run through the station without stopping. The St. Gothard Railway uses control bolts operated by the wire transmission of the signal at all the switches taken from the facing side, which are operated by wire transmissions.
desirable that the posi- n of each blade should checked separately.	It is considered advisable to have control bolts for each of the two blades.	It is preferable to check the position of each blade separately.	It is recommended that the position of each blade should be tested separately, although at present the practice is to check the position of the switch as a whole.	As a rule, the position of the switch as a whole; only in exceptional cases (when the switches are more than 400 metres (437 yards) from the cabin) is the position of each blade checked separately by means of Sigle indicators. The St. Gothard Railway pronounces in favour of checking the position of each blade.
ralized locking is as not used.	At the end of 1907 there were about 700 switches with centralized operation and about 1,700 with centralized locking.	Centralized locking is as a rule not used. As a substitute, on the lines under the Administration of the State Railway, the switches are locked by a key, which is in the cabin, electrically locked from the station (compare answer to question 28). The Moscow-Windau Railway has centralized locking at stations with but little traffic, if the cost is less than that of centralized operation. The Weichsel Railway has about 3 per cent of all the centralized switches bolted.	At smaller stations where the switches have not be thrown over in making various routes; also at stations where there are but few trains.	Centralized locking has as yet been applied but rarely, and then only at stations where this system is limited to individual switches, or where for special reasons the local operation of the switch was preferred to operation from a distance.

QUESTIONS.	Summary of the answers. (Continued.)	
	Germany.	Austria and Hungary.
13. Up to what distance is such locking applied with success, and how long is the corresponding wire transmission?	Up to 500 or 600 metres (547 or 656 yards); with a travel of wire of 500 millimetres (1 ft. 7 11/16 in.). Such locking is even applied (Alsace-Lorraine), with good results, up to distances of 1,350 metres (1,476 yards), with the same travel of the wire.	Up to 550 metres (600 yards), with travel of wire of 500 millimetres (1 7 11/16 in). In Hungary, with the sam travel of wire, up to 500 metres (5 yards).
14. What arrangements are made in connexion with the switch locks, so as to make the cutting open of switches as little injurious as possible?	None.	None.
15. Do you consider it necessary to make arrangements in connexion with switch locks, so that if the locking transmission breaks, the switch is nevertheless kept locked and the setting of the signal is prevented? Have you already such devices in use?	Arrangements for keeping the switch locked if the locking transmission breaks are as a rule not considered necessary, but are partly considered desirable and have been applied in a few cases (Oldenburg). But when a locking transmission breaks the setting of a signal is prevented.	As a rule, no. The Kaschau-Oderbe Railway thinks such devices are to recommended, but it has not yet us any.
16. Have you any arrangements on your system in which a given position of the switch lever releases the switch so that it can be operated locally?	Only in very few cases (Baden).	No.
17. Do you still use single-wire transmission for signals?	No.	No.
18. Up to what distances, on approximately straight sections, do you consider double-wire transmission safe for the operation of signals under all conditions of weather?	Up to 1,200 to 1,500 metres (1,310 to 1,640 yards).	Up to 1,500 metres (1,640 yards).
19. What travel of wire do you use for the operation of signals?	As a rule, 500 millimetres (1 ft. 7 11/16 in). In Oldenburg, 400 millimetres (1 ft. 3 3/4 in.).	As a rule from 250 to 500 millimet (9 13/16 inches to 1 ft. 7 11/16 in.), accordi to the distance of the signals. On t Hungarian State Railway 500 mi metres (1 ft. 7 11/16 in.).
20. Do you operate the main and the distant signal with one double-wire transmission or with two separate transmissions and separate but interlocked levers?	Generally with *one* double-wire transmission and only in special cases (if there is much resistance, also at starting signals) two levers and separate wire transmissions. In Saxony however separate working with two interlocked levers is adopted as a principle. This change is now being adopted in Baden.	Nearly exclusively with two separ wire transmissions and with two in locked levers; only at the Hungar sections of the Southern Railway one double-wire transmission us

Summary of the answers. (Continued.)

Rumania.	Denmark.	Russia.	Sweden.	Switzerland.
nswer to question 12.	Up to 400 and 500 metres (437 and 547 yards), with a travel of wire of 500 millimetres (1 ft. 7 11/16 in.).	On the Moscow-Windau Railway, up to 550 metres (600 yards), (length of wire travel not stated); on the Weichsel Railway, up to 1,200 metres (1,312 yards), with a wire travel of 600 millimetres (1 ft. 11 5/8 in.).	Up to 600 metres (656 yards) (in one case), with a wire travel of 500 millimetres (1 ft. 7 11/16 in.) On the Stockholm-Rimbo Railway the greatest distance is 250 metres (273 yards).	Up to 800 metres (875 yards), on the Swiss Federal Railway without hesitation, with a wire travel of 500 millimetres (1 ft. 7 11/16 in.) On the St. Gothard Railway, up to 200 metres (219 yards), with a wire travel of 450 millimetres (1 ft. 5 11/16 in.).
	None.	As a rule, shearable bolts on the locking bars. On the lines under the Administration of the State Railway, at small stations at which the switches are locked by keys (compare Answer 28), there are shearable pins with electric control indicating the cutting open of the switch and locking the bar operating the signal.	On the State Railway, none. On the Stockholm-Rimbo Railway the transmitting disk at the axis of the lever is uncoupled by the cutting open of the switch.	None.
arrangements are not de, as switch locking not yet adopted: but y are considered necess-y, in case of such lock-, when purely-locking nsmissions are in ques-n, but only condition-ly, if the lock roller at the signal transmis-n.	No.	Arrangements of this sort, as far as switch signal locks are concerned, are considered desirable, but none are as yet used.	Arrangements for keeping the switch locked if the locking transmission breaks are as a rule not considered necessary, but the loking must be so arranged that if the locking transmission breaks it becomes impossible to set the signal to line clear.	Such arrangements are not considered absolutely necessary; up till now none are in use.
	No.	Generally no. Only on the Moscow-Windau Railway, at small stations, are there such switching arrangements.	Yes, rather extensively.	St. Gothard Railway: no. Swiss Federal Railway: yes. This refers to switches much used for shunting operations and difficult to supervise from the cabin.
	No.	No.	No.	No.
o 1,300 metres (1,420 rds). At present howe-only home signals h drop disk mechanic-y replaced (without any cial distant signals) used.	Up to 600 and 700 metres (656 to 765 yards).	Up to 1,500 metres (1,640 yards); on the Weichsel Railway, also up to 2,000 metres (2,187 yards).	Up till now 1,525 metres (1,668 yards) is the greatest distance.	Up to 1,000 and 1,200 metres (1,094 to 1,312 yards).
erly 450 millimetres ft. 5 11/16 in.), more ently 500 millimetres t. 7 11/16 in.).	500 millimetres (1 ft. 7 11/16 in.) for main signals, 250 millimetres (9 13/16 inches) for road signals.	Generally 450 and 500 millimetres (1 ft. 5 11/16 in. to 1 ft. 7 11/16 in.), but also less, down to 209·5 millimetres (8 1/4 inches).	As a rule 400 and 440 millimetres (1 ft. 3 3/4 in. to 1 ft. 5 5/16 in.).	Swiss Federal Railway: 500 millimetres (1 ft. 7 11/16 in.). St. Gothard Railway: 450 millimetres (1 ft. 5 11/16 in.).
e are nodistant si gnals.	As a rule with one double-wire transmission and only occasionally at greater distances with two levers and separate wire transmissions.	Both with a double-wire transmission as well as with two separate transmissions and two interlocked levers. In some parts distant signals are not used.	With one double-wire transmission.	With one double-wire transmission with a division and connexion at the main signal.

QUESTIONS.	Summary of the answers. (Continued.)	
	Germany.	Austria and Hungary.
21. In which cases have you electromagnetic interlocking of the signal and the wire transmission?	With section blocking nearly always in the case of the starting signals, at least for the through main lines and at the corresponding distant signals, in order to prevent, when trains succeed each other rapidly, two trains from starting immediately after each other on the same given signal; moreover in the case of group starting signals applying to departures by various lines; also in order to interlock two succeeding signals if operated separately (for instance starting and distant signal); also at the entrance signals and distant signals on lines *without* section blocking, which join in the open lines *with* section blocking (Saxony). Also in the case of multiple-arm signals, operated by one lever only (Alsace-Lorraine).	At starting signals, which at the sa time are the first signals of a sec blocking system; also at star signals for goods trains from sev tracks, in order to make it necess to operate the signal for each ind dual goods train. Also at electrica operated signals. In Hungary at starting signals of stations, which not protected by interlocking arr gements.
22. Have you made special arrangements so as to make more difficult or impossible any illicit operation of signal wire transmissions outside the cabins?	Apart from wooden or iron protective boxes, none.	As a rule no. The Southern Railv has, instead of stretchers, multiply or reducing levers in use, cove by wooden boxes.
23. In new constructions do you have wire transmissions operation without stretchers?	Only to a very limited extent. In the case of main signals, only if they are on gantries by the cabin. On the other hand, some distant signals up to a distance of 1,000 metres (1,094 yards), are without stretchers. (Wurtemberg), also shunting switches with a transmission less than 200 metres (219 yards) and signals with a transmission less than 400 metres (437 yards) long (Bavaria).	Yes, nearly everywhere without st chers. The Aussig-Teplitz Railv however only omits the use of st chers in the case of signal transi sions less than 200 metres (219 ya long. On the Hungarian section the Southern Railway the use stretchers is limited to distant sig which are a long way off.
24. Have you made any special provision, in order to counteract the disadvantages of the formation of ice at any exposed parts of the switch gear?	Yes, careful drainage of the ground under the transmitting and operating gear which is covered up, sufficiently large spaces between the latter and the ballast; channels and protective boxes wich are open below; openings in the deviation sheaves of the signals.	Yes partly. These disadvantages counteracted by protective cov over the sheaves, also by cases, box tubes, etc. The Hungarian S Railway does not mention any s devices.
25. If the signal wire transmission breaks, does the signal fly automatically to danger?	Yes (Wurtemberg excepted); in Bavaria by the weight of the arm itself.	Yes.
26. In new constructions, do you also use the signal wire transmission for the locking of movable installations (switches)?	Yes, but only to a limited extent. In Oldenburg and Saxony only for the safety locking of entrance switches, which are operated from a cabin at a considerable distance (in Saxony over 300 metres (328 yards).	No.
27. What is the greatest number of switch and signal levers which you have, with satisfactory results, combined in one frame, with hand operation?	Prussia: 87 levers. Bavaria: 90 levers. In Bavaria fewer levers are now preferred, if this does not involve any considerable additional expense.	Austria: 79 levers. Hungary: 40 lev

Summary of the answers. (Continued.)

Rumania.	Denmark.	Russia	Sweden.	Switzerland.
the case of section ocking at the starting gnals.	In the case of automatic return to "danger", or when it is desirable that a signal dependent on one cabin can also be set to "danger" from another point, or when several signal arms are to be operated by one lever.	In the case of electric section blocking at the starting signals, also at the "line clear" disks placed on the entrance signals and operated together with them; also at entrance signals.	In the case of section blocking at the starting signals; in cases this is as yet only intended.	At signals which are far apart, or at through signals placed close to the entrance signal and for which a special lever is not provided in the cabin.
	No.	Yes, locking gear at the stretchers. They are also protected by wooden boxes.	State Railway : no. Stockholm-Rimbo Railway : yes.	Yes.
	Yes.	Only very rarely. Occasionally at signals with wire transmission less than 200 metres (219 yards) long.	Only when the installation otherwise is not so arranged that if a wire breaks the setting of the signal to "line clear" is prevented. Then also in the case of locking when the transmission is shorter than about 100 metres (109 yards).	Swiss Federal Railway : no. St. Gothard Railway : only at distances of less than 200 metres (219 yards).
protective casings or otective covers over all e blocks and cranks.	Yes, these disadvantages are counteracted whenever necessary, by covering the stretchers, blocks, etc.	As a rule, no. Partly wooden protective casings.	Yes, as regards the most northerly parts.	Yes, on the Swiss Federal Railways all deviation blocks, stretchers, cranks and compensating levers, switch locks, etc., are protected by iron covers. The St. Gothard Railway does not mention any special provision.
	Yes, but this system is not universal.	Yes.	Yes, in all new installations.	Yes.
	Yes, for the control locking, where conditions make this possible.	Yes, but rarely	Yes.	Swiss Federal Railway : yes, for the control locking of switches. St. Gothard Railway : no.
evers (and space for more).	70 levers.	About 50 levers.	58 levers.	70 levers.

QUESTIONS.	Summary of the answers. (Continued.)	
	Germany.	Austria and Hungary.
28. Have you any devices in use, or in prospect, which are improvements in hand-operated installations, and which are not referred to in the previous questions?	No.	No.
29-47 : *Power operation.* (Power is used for the actual moving of the signal or switch.)		
29. Have you any signals or switches, in which the operation (the work of the actual moving) is effected by : *a*) Electricity; *b*) Compressed gas (compressed air); *c*) Water unter pressure (liquid under pressure), and the signalman only directs the operation?	Yes, the signals and switches are operated by electricity or compressed gas (compressed air or carbonic acid). Only a few installations of the latter kind are in existence. Operation by liquids under pressure is not used.	Yes, signals and switches are here o rated by electricity or compressed a In Hungaria there is yet only one su installation, and that with compress air.
30. In the case of electric operation of signals and switches, is the power supplied by means of electric motors (state whether continuous-current, single-phase or three-phase current), or by solenoids?	Preferably by continuous-current motors, but in some cases also by solenoids in the case of signals (Prussia).	By continuous-current motors.
31. Can the switches only be moved from one end position to the other, or can they also be moved back from intermediate positions? (Separate answers for cases *a*, *b* and *c*.)	Switches operated electrically or by compressed air can be moved back from intermediate positions. Only in older installations is this not the case.	In the case of the newer installatio switches operated electrically or compressed air can also be mov back from intermediate positions.
32. What is the average time required for throwing over a switch? (Separate answers for cases *a*, *b* and *c*.)	With electric operation 2-3 seconds, with compressed-gas operation 2-8 seconds, according to the distance of the switch and its system of construction.	2-5-4 seconds.
33. Can a switch which has been cut open be again put into normal condition from the cabin, or has this to be done at the switch itself? (Separate answers for cases *a*, *b* and *c*.)	In the newer installations, if a switch operated electrically or by compressed air is cut open, it can again be put into normal condition from the cabin.	In the newer installations, if a swit operated electrically or by compress air is cut open, it can again be p into normal condition from the cab

Summary of the answers. (Continued.)

Rumania.	Denmark.	Russia.	Sweden.	Switzerland.
erence is made to the l contacts, the time con- cts, the electric interloc- ng (including the route erlocking), which are use.	No.	In the lines under the Administration of the State Railway electric devices are used, so that at the cutting open of a switch the signal is at once set to danger. Then also at small stations the locking of the switches by keys, in stead of centralized switch locking, has given good results; the keys are kept in the cabin and released electrically from the station.	No.	No.

29-47 : *Power operation.* (Power is used for the actual moving of the signal or switch.)

er operation is not used.	Yes, by electricity. (At present the is only one such installation.)	Yes, chiefly by electricity. On the Weichsel Railway signals and switches are also operated by liquids under pressure (water in summer, paraffin in winter). They are also a few signals and alarms, which are operated by carbonic acid; some of them are experimental installations.	Power operation is not yet in use.	Power operation is not yet in use.
o.	By continuous-current motors.	By continous-current motors.	Ditto.	Ditto.
o.	The electrically-operated switches can be moved back from intermediate positions.	The electrically-operated signals can also be moved back from intermediate positions and also be moved forwards again.	Ditto.	Ditto.
o.	Two seconds on the average.	2 1/2-3 seconds in the case of electric operation. 3 seconds in the case of liquid under pressure.	Ditto.	Ditto.
above.	The electrically-operated switches can again be put into normal condition from the cabin.	As regards the installations on the lines under the Administration of the Russian State Railway the electrically-operated switches can again be put back into normal condition from the cabin. At regards the installations on the Warsaw-Vienna Railway, and the switches operated by liquid under pressure of the Weichsel Railway, putting back the switches into normal condition has to be done at the switch itself.	Ditto.	Ditto.

QUESTIONS.	Summary of the answers. (Continued.)	
	Germany.	Austria and Hungary.
34. Is the electric control of the position of the switch arranged so that it only checks the completion of the operation of the switch as a whole, or so that it checks the correct position of each of the two blades?	Both systems are in use. In the cases of switches taken by passenger trains from the facing side, it is usual to check the position of each of the two blades.	Both systems are in use. In the ne installations the control is so arran that the position of each of the blades is checked.
35. Do you operate all the switches concerned in a given route simultaneously (by the route lever), or do you limit the simultaneous operation to every two related switches, or do you have all the switches operated separately?	As a rule switches are operated separately; but two related switches are also operated simultaneously.	As a rule each switch is operated parately; simultaneous operation limited to two switches.
36. Has the simultaneous operation of several switches proved satisfactory?	As regards the mechanical installations, quite satisfactory; particulary if the two motors of the related switches are so connected that one works after the other.	The simultaneous operation of switches, having their motors coup up in parallel, has given rise to difficulty.
37. In the case of shunting operations, for which the route locking and the signals are not used, is the arrangement made that when several related switches are set simultaneously, the failure of one to attain its correct position, also prevents the moving of the others?	Not as a rule. In the case of the abovementioned successive working of the two motors, if the switch acted on first fails to attain its correct position, this also prevents the moving of the second switch.	No.
38. Have the power installations in use given satisfactory economical results or the reverse : *a*) as regards labour; *b*) as regards maintenance; *c*) as a whole?	As regards labour, economical advantages nearly in all cases; as regards maintenance, economical disadvantages, according to local conditions. In Wurtemberg, also, the maintenance has proved advantageous economically.	Economical results both as regards bour and as regards maintenance.
39. Have they facilitated the working of the service?	Nearly generally : yes. But Bavaria answers in the negative.	Yes.
40. Have they made it possible to effect a saving in staff, and to what extent?	In Prussia, this varies with the local conditions. In Alsace-Lorraine, as working-hours could be extended, a saving of about 20 per cent in labour was effected. In Wurtemberg from 1 to 2 men less are required at every cabin. In Bavaria and Saxony, none.	Austria gives no answer; as rega Hungary, yes, about one third.
41. Are failures more frequent or less frequent than in the case of hand-operation?	As a rule more frequent.	Rarer; certainly not more frequent.

Summary of the answers. (Continued.)

Rumania.	Denmark.	Russia.	Sweden.	Switzerland.
bove.	The control only checks the completion of the whole operation.	As a rule, only the completion of the whole operation of the switch is checked; but the system of checking the position of each blade separately is also in use. In the case of the switches operated by liquid under pressure there is no electric control.	See above.	See above.
bove.	Simultaneous operation is only used in the case of two related switches.	As a rule the switches are operated separately: two related switches are also operated simultaneously. In the case of the switches operated by liquid under pressure, separate operation alone is used.	See above.	See above.
bove.	No answer is given.	Very satisfactory; but as yet not more than two switches are operated simultaneously.	See above.	See above.
bove.	No.	There is no decided answer.	See above.	See above.
bove.	As a whole, economical results.	The electrically-operated installations (of which there is as yet but one on the Russian State Railway system) are simpler to operate, but require more careful maintenance: this however is an advantage from the point of view of the safety of the traffic. There is an economical advantage as regards the maintenance of the transmission. Disadvantages: great initial cost. Installations operated by liquids under pressure are all more costly.	See above.	See above.
bove.	Yes.	Yes.	See above.	See above.
bove.	The one existing installation is new; consequently the question can not yet be answered.	On the State Railway system: 25 to 30 per cent, when larger installations are considered. On the Warsaw-Vienna Railway and on the Weichsel Railway: no.	See above.	See above.
bove.	More frequent.	On the State Railway system, less frequently; on the Warsaw-Vienna Railway and on the Weichsel Railway, more frequently.	See above.	See above.

*

QUESTIONS.	Summary of the answers.	
	Germany.	Austria and Hungary.
42. What kinds of failure occur most frequently?	Incomplete making of contacts in consequence of deformation or dirt; blowing of the fuses, fusing of cable wires of the motor leads, fracture of the contact springs; failure of the control of the blades, resulting from the pressure of foreign bodies at the blades or from movements of the track; burning-out of the field magnets and destruction of the insulating bushes. Trouble with the magnetic couplings and the charging apparatus. In the case of pneumatic operation: loss of tightness of the operating pistons.	Failures as a rule only occur with insulated rails. Wear of commuta and loosening of the terminal scre are also mentioned.
43. Does their correction take a longer or shorter time than in the corresponding failures in the case of hand operation?	As a rule less time, if the employee entrusted with the work is on the spot. In the case of smaller installations in Bavaria, more time. Alsace-Lorraine and Saxony state that sometimes considerable time is lost in trying to find the faults.	Shorter.
44. Is a specially-equipped mechanic kept on the spot to attend to the ordinary maintenance of the installation and to do smaller repairs, or does the usual permanent-way maintenance staff suffice for this purpose?	Specially-trained men (mechanics labourers) are kept on the spot, who have obtained the necessary experience (if possible, when the installation was constructed).	Specially-trained men are kept at larger stations; at the smaller o the ordinary permanent-way mai nance staff suffices.
45. Have you also, in connexion with hand-operated installations, equipped individual appliances which have to be set from a gret distance, for power operation, and with what success?	Yes, single signals with good success. Partly however this has only been done as an experiment, so that no opinion as to success can yet be given.	No.
46. What improvements in power installations do you consider desirable and practically possible?	No special improvements are described; but Alsace-Lorraine mentions as desirable the better protection of the appliances against dust and dirt, and the stronger construct on of the cases containing the motors, for more effective protection in cases of derailment. Saxony recommends that the power installations should be designed in such a way that simple-phase current can also be used.	(There is no answer from Austria.) The Hungarian State Railway has o one installation, of older constructi and is not in a position to mention improvements on those already at ned in the newer installations.
47. In the case of new constructions, to you consider the use of power installations, and to what extent? Which system do you prefer?	Yes, if in cases of much traffic the signalmen would be overworked in case of hand operation, or would have to be increased in numbers, at additional expense, and if electric power is available. Then also at large stations with many block sections and much traffic. At present the question is as yet partly undecided. Experiments made to determine whether installations operated purely electrically, or installations operated pneumatically but controlled electrically, are to be preferred, are not yet completed; but as a rule there is a tendency in favour of purely-electrical operation.	Yes, at stations with many block s tions and very much traffic, and stations where the construction maintenance of long transmission very difficult and costly. The electric system is on the whol be preferred. In Hungary the inv tigation of this question has not been completed.

Summary of the answers. (Continued.)

Rumania.	Denmark.	Russia.	Sweden.	Switzerland.
ove.	Failure of contacts, short-circuiting of the magnet windings, blowing of fuses.	Blowing of fuses; premature operation when vehicles are on the track; failure of the apparatus owing to defective insulation, to the formation of ice at the external electric contacts. When liquid under pressure is used: leakage of the water under pressure and dirt.	See above.	See above.
ove.	About as long.	State Railway system: as a rule shorter, because all the parts concerned can be renewed more easily. Warsaw-Vienna Railway and Weichsel Railway: longer.	See above.	See above.
ove.	A mechanic seems necessary in addition to the ordinary maintenance staff.	According to the experience of the Administration of the State Railway the ordinary permanent-way maintenance staff suffices, but must be well equipped. But both the Warsaw-Vienna Railway and the Weischel Railway keep a special mechanic.	See above.	See above.
ove.	No.	Yes, several signals which are very far off are operated by carbonic acid, and that with very good results.	See above.	See above.
ove.	That the moter should be freely accessible and above ground, and that the position of both blades of the switch should be checked.	Generally speaking no recommandations are made; the Warsaw-Vienna Railway however considers as desirable arrangements for automatically stopping a train at a main signal if this is standing at »danger«.	See above.	See above.
ove.	Yes.	As a rule, no. The State Railway, only in the case of large stations; and in such cases operation by electric motor (not solenoids) is taken into consideration.	See above.	See above.

QUESTIONS.	Summary of the answers. (Continued.)	
	Germany.	Austria and Hungary.
48-65 : *Signals and switches generally.*		
48. In which cases do you use electric controls for checking whether the operation of the signal has been carried out correctly?	Some managements use them at all signals which are at a considerable distance; but always when the signal is operated by power. In the case of hand-operation, as a rule, when the signalman cannot see the signal. Baden uses them for informing the general traffic office when a main signal has been operated from a signal cabin; also for the information of the signalman himself, if the main signal does not possess any coupling arrangement, the circuit of which is broken when the signal is lowered. Alsace-Lorraine uses these controls on all entrance signals, Saxony on main signals with long transmission, if the signalman cannot see them. Bavaria uses in the case of hand operation electric controls for checking the position of the signal lever, if the operation is not carried out under the supervision of the signal cabin; then also in special cases there are electric controls for checking the position of the starting signals.	When signals are not interlocked also cannot be seen by the signalm Then these controls are also specia used in the case of all entrance gnals, and in cases also for start signals. On the Hungarian St Railway such controls are used ge rally.
49. Does this control apply to the « danger » position of the signal, or does it also apply to the « caution », « proceed slowly », and « line clear » positions?	As a rule to the « danger » and « line clear » positions, in a number of cases to the « danger » position only. Exceptionally (in Bavaria, in cases of hand-operation) it is limited to the « line clear » position.	As a rule only to the « danger » positi (On the Hungarian lines of the A trian Southern Railway it also plies to the « line clear » position.)
50. Is there also such an electric control to show that the signal lantern is burning or is such an arrangement, in consequence of the experience gained, being taken into consideration?	No.	No.
51. Is the signal-control current, or its interruption, also utilized for locking purposes in the cabin?	No.	No.
52. Have successful attempts been made materially to increase the illuminating power of the signal lanterns as compared with the present average, and if so, in which way?	Yes, in Baden with reflectors 240 millimetres (9 7/16 inches; [instead of 150 millimetres (5 15/16 inches)] in diameter; and Saxony with special unsymmetrical reflectors. Further experiments are being made.	No.
53. In what cases do yon use specially-strong signal lights?	Specially-strong signal lights are as a rule not used. Baden alone is using them of base for distant signals.	In no case.

Summary of the answers. (Continued.)

Rumania.	Denmark.	Russia.	Sweden.	Switzerland.
48-65 : *Signals and switches generally.*				
rule at entrance and rting signals (the con- ls used are on the nk patent system, plied to Siemens & lske installations).	When the signal cannot be seen by the employee responsible for its operation.	Principally in the case of signals which can only be seen with difficulty, or not at all, from the signal cabin or by the employee operating the signal. The Warsaw - Vienna Railway uses such controls in the case of all main entrance and starting signals; the Moscow-Brest Railway, in the case of all centrally-placed signals.	Such devices are not used	In the case of all entrance signals, exceptionally also in the case of starting signals, which cannot be seen by the employee operating them.
ne « danger » and the ne clear » positions.	Only to the « danger » and the « line clear » positions.	Nearly exclusively to the « danger » and « line clear » positions.	See above.	In the case of older installations only to the « danger » and « line clear » positions; in the newer installations also to other intermediate positions.
	No.	As a rule, no. Only in the case of electrically-lighted signals, on the lines of the State Railway, are there control lights in the signal cabin.	See above	Only in the case of electrically-lighted signals. The Swiss Federal Railway only uses them in the Simplon tunnel.
	No.	As a rule, no.	See above.	No.
	No.	As a rule, no. On the Warsaw-Vienna Railway electrically - lighted signals have given good results; the experiments with acetylene lighting did not give satisfaction.	No.	On the Swiss Federal Railway, none. The St. Gothard Railway is beginning to replace its 10-line burners by 14-line burners.
are not used.	They are not used.	The Weichsel Railway uses them for entrance and for starting signals. The Warsaw-Vienna has as yet only made experiments.	It has never been necessary to use specially-strong lights.	In tunnels, especially under bad smoke conditions.

QUESTIONS.	Summary of the answers. (Continued.)	
	Germany.	Austria and Hungary.
54. Have you taken any special measures for preventing the fracture of the signal-light glasses ?	Yes, lead and rubber settings. The signal arms and disks are equipped with check springs and counterbalanced so as to reduce shocks. In addition wire glass is also used, especially for distant signals.	Yes, wire glass and elastic settin the glasses.
55. In case of failure, are the switches also arranged for hand-operation on the spot, and how : *a*) In the case of hand-operation? *b*) In the case of power-operation?	In most cases the only arrangement made is that a hand lever can readily be fixed on the spot. In Saxony the hand lever is already fixed, but disconnected from the switch. In cases of electric operation the motor can be turned by a cranked handle. In addition, in some cases (Sax hand levers are put up alongside, which can be quickly joined up afte electric gear has been disconnected. In the case of compressed-air operati hand lever can be fixed in cases of failures.	Yes, the hand lever can easil fixed.
56. Do you also operate from your cabins switches with blade but without heel chair (spring switches) ?	Yes, but partly (in Saxony, Wurtemberg and Baden) only as an experiment. Spring switches are not used in Bavaria.	Yes, experimentally on the Railway.
57. Are arrangements made to prevent any injurious action of the elastic force of such switches on the operating gear : *a*) In the case of hand-operation ? *b*) In the case of power-operation ?	Not in the case of hand-operation, but in some cases of electric operation there is an elastic friction catch, which holds the operating rod in its final position (trials in Alsace-Lorraine). In the case of electro-pneumatic operation the existing pressure of the air suffices.	No answer.
58. Do you also operate from your cabins barriers and level-crossing gates, and are they then included in the route interlocking ?	Yes, but as a rule only the barriers are included in the route interlocking.	Yes, but only the barriers are incl in the route interlocking, while l crossing gates are separately l locked with their signals. In the case of barriers locking is s times adopted instead of setting a distance.
59. Are any arrangements provided, by means of which the locomotive driver is specially informed : *a*) That he is approaching an optical signal ; *b*) That the optical signal he is passing is standing at « danger », or « caution », or « proceed slowly » ? This in addition to the appearing of these signals and the use of detonators placed by hand on the track. What are these arrangements ?	Yes, placing the detonators on the track by a lever machine. The appearing of several very bright lanterns. Contacts and impacts, which operate alarms and visible signals on the locomotive. (Experiments with the Braam signalling devices.) Gongs at the distant signals in places where there is much fog (partly already discarded).	No.
60. Do you in some cases, before the definite signal, provide means of communication in order quickly to give information to a train which has stopped (electric syrens, etc.), without the agency of a signal cabin or arrangements for connecting up a telephone line?	Yes, to transmit the signal « wait », electric systems are in some cases used (Prussia and Saxony).	No.
61. Are any means provided which make it possible to catch a train which is not stopping or probably is not going to stop at the spot it should stop at?	Yes, sand tracks and hydraulic buffer stops in Prussia. Sand tracks and experiments with double skids in Saxony.	Austria : no. Hungary : sand tr in a few cases.

Summary of the answers. (Continued.)

Rumania.	Denmark.	Russia.	Sweden.	Switzerland.
	Yes, wire glass.	Yes, wire glass and lead setting; also setting wholly in wire work; but such measures are as a rule not taken.	No.	Yes; the Swiss Federal Railway uses metal frames and in addition putty or leather settings. Experiments with wire-work settings did not give satisfactory results.
	Not in the case of hand-operation; in the case of electric operation by a hand lever after removal of the motor.	In the case of hand-operation, on the lines under the Administration of the State Railway, no; otherwise generally yes. In cases of electric operation, the motor can be turned by a cranked handle.	No.	On the Federal Railway, only in the case of a few of the older wire-transmission installations. The switch is the operated by a crank swung horizontally, which is connected with the operating gear by a pinion and bevel gear. On the St. Gothard Railway by the existing gear.
switches with rotating ades, fished, are used.	No.	No.	No.	No.
56.	Spring switches are not used.	There are no spring switches.	There are no spring switches.	There are no spring switches.
barriers are included the route interlocking.	Yes, in a few cases.	As a rule yes, but generally only the barriers are included in the route interlocking.	Yes, the barriers are always included in the route interlocking, the level-crossing gates only rarely.	Yes, but as a rule only the barriers are included in the route interlocking.
	No.	No (apart from detonators).	No.	No.
	No.	No.	No.	No.
	Yes, sand tracks under special conditions.	Yes; for trains, sand tracks; for separate vehicles centrally-placed skid blocks and throw-off switches. Reference is also made to hand signals and detonators.	No	o.

QUESTIONS.	Summary of the answers. (Continued.)	
	Germany.	Austria and Hungary.
62. Do your trains automatically act on the signalling and switching gear? *a*) Advice of its approach? *b*) Blocking or unblocking action (apart from the measures considered under B)?	*a*) Only in solitary cases, by means of rails contacts. *b*) Yes. The passage over rail contacts either affects the block fields and unlocks them or the current is interrupted in the case of the signals fitted with gear for automatically flying to "danger".	*a*) As a rule not. Only the South Railway uses for the purpose appa tus and alarms for notifying approach. *b*) Yes. The passage over rail conta releases the magnetic locking o block field, so that it can then be c rated. The Southern Railways also in a few cases track-block appliances, which after the train passed an entrance signal blocks line until the entrance has been c pleted, and only allow the signal be set to "line clear" after the tr has departed. On the Kaschau-Od berg Railway the train exercice releasing action on the switching signalling gear.
63. What arrangements are made to make the setting of a signal to "line clear" dependent on the co-operation of the traffic manager?	As a rule releasing gear, which has either to be operated by the traffic manager himself or acted upon by interlocking. Prussia and Oldenburg very frequently use for this purpose keys, with which the traffic manager unlocks the corresponding field of release. In Saxony the so-called "assenting contacts" (Zustimmungskontakte) are in use, by means of which the traffic manager completes the circuit for the electric locking of the correct route, and at the same time makes it possible to set the corresponding signal to "line clear".	As a rule, releasing appliances wh have to be operated by the tra manager himself.
64. What arrangements have given the best results, in cases where many shunting operations are carried out, for obtaining a mutual understanding between the different inclines and the switches of the corresponding sorting sidings?	Mechanically-revolved large shunting disk indicators, with numbers on them; loud-speaking telephones, electric track indicators. In Bavaria there are also used disks with inscription hung on to the buffers.	In Austria, as a rule, special arran ments of this kind are not in use. Aussig-Teplitz Railway alone us in addition to the usual hand and h signals, special tickets, hand bells alarm signals. In addition, the p sage of the switch-limit marks of sorting sidings is indicated in signal cabin, by ringing special con bells, which are put into circuit by passage over special rail contacts. On the Hungarian State Railway, e tric indicators are used as track in cators.
65. Have you recognized as desirable, or tried, or taken into consideration, any further improvements in switching and signalling appliances besides those considered here; and if so, which?	Generally speaking, no.	No.

A. — II.

66-77 : *Electric interlocking of route levers.*

66. Do you principally use mechanical or electrical interlocking of the route levers?	Chiefly electrical interlocking. In Wurtemberg chiefly mechanical interlocking. In Bavaria at small stations up to distances of 400 metres (437 yards), mechanical, and at greater distances electical interlocking.	Chiefly electrical interlocking.

Summary of the answers. (Continued.)

Rumania.	Denmark.	Russia.	Sweden.	Switzerland.
). s. The passage over eadle sets the entrance ials mechanically to nger".	*a*) In some cases. *b*) Yes, to set free route levers and blocks.	Yes. *a*) By optical and acoustical signals sent to the signal cabin or station. *b*) By releasing routes and the locking of block fields: rail contacts and, experimentally, treadles. On some of the railways arrangements for this purpose are not provided.	*a*) Yes. *b*) Yes, to release blocks and the electric locking of route levers.	No.
e 1900, mechanical ises; after 1900 alter-ng-current block ap-tus for the electric se of the signals.	Electric interlocking gear	As a rule releasing appliances, which have to be operated by the traffic manager himself.	At smaller stations no special arrangements are made. At larger stations electric interlocking gear is used. Trials with mechanical interlocking gear did not give satisfactory results.	On the Swiss Federal Railway there is, as a rule, mechanical release of the route; on the St. Gothard Railway the consent of the traffic manager is, if necessary, obtained by telephone.
hones.	Loud-speaking telephones.	On the lines under the Administration of the State Railway and on the Warsaw-Vienna Railway loud-speaking telephones are used; the former also uses needle indicators. The Weichsel Railway uses for this purpose the ordinary optical and acoustical signals.	Such do not exist at shunting yards.	The understanding is arrived at by writing the number of the sorting siding desired on the buffer, or else verbally.
	At present not.	Generally speaking, no.	No.	No.

A. — II.

66-77 : *Electric interlocking of route levers.*

nical interlocking by ng, released electri-(by alternating-cur-fields).	Mechanical interlocking by slotting, released electrically.	Chiefly electric interlocking. The Ssysrau-Wjasma Railway chiefly mechanical.	Chiefly electrical interlocking.	Chiefly mechanical and only exceptionally electrical interlocking.

QUESTIONS.	Summary of the answers. (Continued.)	
	Germany.	Austria and Hungary.
67. Are only the entrance-route levers interlocked, or also the departure-route levers?	The entrance-route levers nearly all; frequently both. In Prussia, the departure-route levers only partly. In Oldenburg, only the entrance-route levers.	Both.
68. Is the electric interlocking of a route effected by the signalman by a separate operation, or does it result automatically from the operation of the levers?	As a rule by the signalman by a separate operation; but also automatically, as in Baden and to some extent in Bavaria. In the case mechanical station blocking automatically; the same in the case of power-operation.	As a rule by the signalman by a separate operation. On the Austrian Railway exclusively automatica the case of power-operation.
69. In the former cases, is the signalman compelled to carry out this operation, and if so, how?	Yes, the electric interlocking of the route lever has as a rule to be effected before the signal can be set to « line clear ». The compulsion to interlock electrically the route lever in the « danger » position, which presents the operation of the signal, is effected either by the interlocking of the block sections or by the signal moving automatically to « danger ». Another compulsion exists in the interlocking with the traffic-manager apparatus.	Yes, the electric interlocking o route has to be effected befor signal can be set to « line clear »
70. Do you use for this interlocking continuous-current or alternating-current apparatus? When the one and when the other?	Chiefly alternating-current apparatus; in Wurtemberg only continuous-current apparatus. Prussia, in the case of power installations, uses continuous-current interlocking apparatus.	In the case of hand-operation, alt ting-current apparatus, in the ca electrical operation, continuous rent apparatus.
71. Do you use electric interlocking of the route levers also in the « line clear » position in order to prevent the premature operation of switches?	Yes. (See also 69.)	Yes.
72. How and from where is this then released, and do you also let such interlocking be released by the train automatically?	As a rule by means of a special alternating-current (releasing) field after the arrival or departure has been completed. The release is effected from the station or from a cabin. Automatic release by the train is also used, in Wurtemberg and Alsace-Lorraine exclusively.	As a rule by the traffic manage means of a special alternating-cu (releasing) field. On the Southern Railway automat lease by the train is also used.
73. Have you any arrangements which make it possible to interlock groups of several route levers by one common appliance?	Yes, but not generally. But the interlocking of routes which mutually exclude each other is often effected by one common appliance. In Saxony such common interlocking appliances (groupe blocking) are used extensively.	Austria : yes. Hungary : no.

Summary of the answers. (Continued.)

Rumania.	Denmark.	Russia.	Sweden.	Switzerland.
.	According to the conditions, both.	Both.	Both.	Both. On the Federal Railway the entrance-route levers are mechanically interlocked in both the « line clear » and the « danger » position. The interlocking in the « line clear » position is effected by a special locking field, which is released by the passage of the train.
interlocking is effected tomatically by the moment of the lever.	Both system are used.	As a rule by the signalman by a separate operation. On the lines under the Administration of the State Railway and on the Weichsel Railway both systems are used.	As a rule by the signalman by a separate operation.	As a rule, automatic interlocking resulting from the operation of the lever.
nswer 68. See also 72.	Yes, the interlocking of the route has to be effected before the signal can be set to « line clear ».	Yes, the interlocking of the route has to be effected before the signal can be set to « line clear ».	In the case of electric interlocking of the route, this has to be effected before the signal can be set to « line clear ».	The Federal Railway gives no answer. The St. Gothard Railway has no such arrangements.
rnating-current apparus.	Continuons-current apparatus if the interlocking is mechanical or automatic; otherwise alternating-current apparatus.	Chiefly alternating-current apparatus. On the lines under the Administration of the State Railway, in the case of electrically-operated installations, continuous-current apparatus is also used.	Chiefly alternating-current apparatus. The State Railway however uses continuous current for interlocking the route lever for the « line clear » position; this is automatically released by the train.	On the Federal Railway, alternating current exclusively is used in the case of electric station interlocking; continuous-current is only used in the case of blocking fields which are automatically released by the train. The St. Gothard Railway has only continuous-current apparatus.
	Yes.	Yes.	As a rule, no. Up till now the State Railway has only one such apparatus, but several more are planned.	Federal Railway : yes (see 67). St. Gothard Railway : no.
ays by the train mana- by means of a special ernating-current (re- sing) field.	As a rule by the train, sometimes by the station-master.	As a rule by the traffic manager; sometimes (Warsaw-Vienna Railway) in conjunction with action by the train. On the Moscow-Windau Railway and on the lines under the Administration of the State Railway automatic release by the train is also in use.	As a rule by the train; only in one case by the station-master.	(No answer.) Note : According to answer 67, the release in the case of departures is effected by the train.
	Yes.	As a rule, yes.	No.	Federal Railway yes. St. Gothard Railway : no.

QUESTIONS.	Summary of the answers. (Continued.)	
	Germany.	Austria and Hungary.
74. Do you combine with route-lever operation the closing of any contacts, and if so for what purpose?	Yes, for closing the circuit of the battery through electrical coupler and electrical blocks; also for effecting the continuous-current route interlocking; for other interlocking; for completing the circuit, in group blocking, which has partly been made by the traffic manager or by the second signalman.	Yes, for closing the circuit of the ductor switched in by the tr manager, as well as for closing circuits which are required for given route.
75. Have you any electric interlocking of signals or switches which is effected without the action of the route lever?	Apart from block section signals, only exceptionally or in older installations. It is proposed in Prussia to introduce such interlocking in cases of power-operation.	Yes, but generally only in cases w the signals are not directly interlo with the switches, or in cases of simple installations.
76. Has the *a*) electrical, *b*) mechanical, route-interlocking used given good results, and does it also seem suitable for a very busy traffic?	Electric interlocking has proved satisfactory, particularly also for a very busy traffic, and is generally preferred to mechanical interlocking. The latter has, it is true, also given satisfactory results on the whole, but is not, in Prussia for instance, to be used in the future.	The electric interlocking used ne everywhere has given good and r ble results. On the Aussig-Te Railway, mechanical route-interl ing has also proved sufficient at tions with switch interlocking a gements.
77. What system of route-locking, or what arrangements for replacing it, would you recommend in the case of new installations?	As a rule, electrical interlocking. Satisfactory results have also been obtained (Bavaria) by automatic locking produced by the operation of the route lever.	A a rule, the usual (electric) i locking.

B.

78-94 : *Measures taken to prevent the operation of switches, whether taken from the facing or fr the trailing side, before the whole of the train has passed over them.*

78. Have you put in any devices of a purely mechanical nature, to prevent the moving of switches before the whole of the train has passed, *a*) when taken from the facing side; *b*) when taken from the trailling side: and of what kind are they?	Yes, as a rule pressure or contact treadles, particularly in the case of switches taken from the facing side. In Bavaria these mechanical devices have recently been replaced by electrical devices. Prussia and Oldenburg also use time locks for this purpose.	Austria: yes, pressure treadles in case of switches taken from the fa side; these are however no lo used by the Austrian North Wes and South Northern. The Au Teplitz Railway also uses pres treadles with special lever for d mining that the track is clear a switch-boundary mark. Hungary: No.
79. Are there any devices in use, which as soon as the first wheels pass on to the switch, lock it for a certain time, and after this time has elapsed, release it again?	Yes, time locks. Time locks which were used in Saxony and Baden as an experiment were removed owing to technical and operating difficulties.	As a rule, no.
80. Are mechanical devices (pressure or contact treadles, running rails with canting motion, etc.) used in combination with the electrical?	Yes, in individual cases, to form a substitute for an insulated rail. Pressure treadles are in use combined with rail contacts and continuous-current locking fields; electric lever locks at the treadle levers; canting rails acting on electric contacts to release blocking.	As a rule, yes. The Austrian N Western and South Northern pressure and contact treadles, in bination with insulated rails; Southern Railway contact tre rails. The Hungarian State Railway are using such devices experimentall

Summary of the answers. (Continued.)

Rumania.	Denmark.	Russia.	Sweden.	Switzerland.
or closing the circuit e battery through the rical coupler, and establishing the cor- circuits in the case oup blocking.	Yes, for instance for the electric interlocking of signals.	Yes, for signals contacts, insulated rails, coupler circuits; for changing the block field circuits; also in order to reduce the number of electric conductors, and to check the correct making of the route.	Yes, for the electric couplers at the starting signals in cases of section blocking, also for interlocking the route lever by means of a continuous-current field.	Federal Railway: Yes, occasionally for trough routes. St. Gothard Railway: No.
	Yes, in a few cases.	On the State Railway this is only used for signals; on the Weichsel Railway only for minor installations. Otherwise not.	No.	No.
	As yet there is not enough experience, but the question will probably be answered in the affirmative.	Electrical interlocking has proved advantageous. The Ssysran-Wjasma Railway uses mechanical interlocking exclusively, which works well.	The State Railway has as yet not enough experience. The Stockholm-Rimbo Railway answers the question, as far as electrical route-interlocking is concerned, in the affirmative.	Yes, both kinds of interlocking have given good results and satisfy stringent requirements.
Bruchsal system of truction is recom- ded.	The subject is here still in the experimental stage.	Electric interlocking. (The Siemens and Halske gear is specially recommended.)	As yet there is not enough experience.	The Federal Railway gives no answer. The St. Gothard Railway gives electric interlocking the preference.

B.

-94 : *Measures taken to prevent the operation of switches, whether taken from the facing or from the trailing side, before the whole of the train has passed over them.*

f required contact lles and also time are used (see 28).	Yes, contact treadles as an experiment in the case of switches taken from the facing side.	As a rule, no. Experiments made by the Warsaw-Vienna Railway did not prove satisfactory. The Weichsel Railway uses treadles.	Yes, contact treadles or so called treadle rails in the case of switches taken from the facing side. The State Railway also uses time locks for this purpose.	Federal Railway: Yes, contact or pressure treadles, also time locks (pneumatic), in the case of switches taken from the facing side. St. Gothard Railway: pressure treadles are being tried experimentally in the case of switches taken from the facing side.
ime locks at those hes at which contact lles can not be used.	Yes, experimentally.	Yes, on the State Railway insulated rails, on the Weichsel Railway time locks.	Yes, on the State Railway; time locks.	Time locks (pneumatic), only on the St. Gothard Railway, as an experiment.
	No.	As a rule, no; on the Warsaw-Vienna Railway only experimentally.	No.	In some cases of the route locking, balanced contact rails connected with the electric lever locks.

QUESTIONS.	Summary of the answers. (Continued.)	
	Germany.	Austria and Hungary.
81. What do you consider the correct length of the pressure or contact treadles?	11 metres (36 ft. 1 in.), occasionally more. In Saxony, 13·5 metres (44 ft. 3 1/2 in.); in Wurtemberg 15 metres (49 ft. 3 in.).	Generally 10 metres (32 ft. 10 in.) given as the correct length. T Aussig-Teplitz also uses treadles fr 6 to 12 metres (19 ft. 8 in. to 39 ft. 4 i long, according to the wheelbase of t vehicles. The Hungarian State Ra way pronounces in favour of lengt exceeding 12 metres (39 ft. 4 in.).
82. What lengths have already proved satisfactory from the point of view of construction?	Lengths of 11 metres (36 ft. 1 in), also of 13·5 metres (44 ft. 3 1/2 in.) (Saxony) and 15 metres (49 ft. 3 in.) (Wurtemberg).	Lengths of 10 metres (32 ft. 10 in Under some conditions lengths 7 metres (23 feet) suffice and pro satisfactory. In any case the leng must at least be equal to the great standard wheelbase. In Hungs there is as yet not enough experienc
83. Have such treadles also been used with good results at curves?	Yes, with good results at curves with diameters down to 300 metres (15 chains); in a few cases with results which only just sufficed, down to 180 metres (9 chains). Some managements do not use them on curves.	Yes. According to the experience of t Austrian Southern Railway they ho ever require more frequent inspe tion, as rail-creeping easily produc jamming.
84. Are also purely-electrical devices in use for the same purpose?	Yes, in the case of power-operation, insulated rails (by themselves or in combination with rail contacts before the switches, and when the train passes on to the former, the switch lever is locked; in the case of hand-operation the route rod is locked by an electric block field. Alsace-Lorraine also uses for the purpose the electric lever lock at the switch or the route lever. Bavaria in more recent times uses the same locking gear also to release the route, in combination with a mechanically-acting wheel contact.	Yes.
85. How is it arranged, that the action does not terminate before the last axle has passed; for instance if the train stops?	By the use of insulated rails or by having a corresponding distance between the switch and the rail contact before it.	By the use of insulated rails or having a corresponding distance b ween the switch and the rail cont in front of it.
86. Do you also use insulated rails for this purpose?	Yes, but not generally.	As a rule, yes.
87. Do you also use insulated rails for other purposes, and if so, which?	Besides the chief purpose, which is to maintain the route locking or the switch locking until the train or vehicle has left the insulated rail, they are also used for the release of electric blocking keys or block fields, also for releasing electric signal-arm interlocking. In Wurtemberg the insulated rail is also used for indicating the departures of trains.	Yes, in the case of section blocking a for releasing routes. In addition th are also used by the Austrian Sou ern Railway for locking the entra route till the entrance has been co pleted and in order to prevent release of the same signal, till af the train has left; also to oper indicators and bells notifying approach of a train.
88. What system of fishing has given the best results with you?	As a rule wooden fishplates made of hornbeam or of Australian hardwood with special stops for preventing creeping. In Saxony the action of the wooden fishplate is reinforced by a short longitudinal sleeper of oak supported on iron transverse sleepers.	As a rule, wooden fishplates of ho beam. On the Austrian Southe Railway, wooden framing under joint has also given good results.

Summary of the answers. (Continued.)

Rumania.	Denmark.	Russia.	Sweden.	Switzerland.
res (36 ft. 1 in.).	Experiments in this direction have only just begun.	10 to 11 metres (32 ft. 10 in. to 36 ft. 1 in.). As yet experience is limited.	The length must exceed the longest wheelbase.	Lengths of 12 metres (39 ft. 4 in.) are considered sufficient.
ıs of 11 metres (36 ft.).	See supra.	Lengths of 11 metres (36 ft. 1 in.). As yet however experience is limited.	Lengths of 13·5 metres (44 ft. 3 ½ in.).	Lengths of 12 metres (39 ft. 4 in.). But the question is not yet quite settled.
large-radius curves, e treadles are placed the superelevated	See supra.	No.	(No answer).	Contact treadles at curves do not seem advisable, hence are not used.
	Yes.	Yes, generally, such as : insulated rails, rail contacts, electrical locking apparatus for locking the switch or route levers.	Yes, rail contacts combined with continuous-current apparatus for locking the route lever in the route position (see 70).	Yes, rail contacts combined with continuous-current apparatus for locking the route lever in the route position. (See Nos. 67, 89 and 90.)
electric connection veen the rail contact the switch lever.	Special means for this purpose, those mentioned under 86 excepted, are not used.	By the use of insulated rails or of correspondingly-advanced rail contacts.	(No answer).	(No answer).
	Yes.	Yes, but not generally.	(No answer).	No.
n the case of section king, for departing ıs.	Yes, in order to prevent the premature throwing-over of switches and in connexion with rail contacts to release route levers and locking keys.	On the systems of the State Railway and of the Warsaw-Vienna Railway they are used for releasing routes, in the case of the former also for releasing the operation of block sections.	Special rails (insulated rails ?) are used in Sweden, together with bent-rail contacts for the release of the gear which locks the route levers in the position for the route. It is also proposed to use insulated rails for releasing electric couplings at starting signals in the case of section blocking, which is going to be introduced.	No.
sual wooden fishpla-	Wooden fishplates of Messrs. Siemens & Halske.	Wooden fishplates (pickled).	Enough experience is not available.	Insulated rails are not used.

QUESTIONS.	Summary of the answers. (Continued.)	
	Germany.	Austria and Hungary.
89. When special rail contacts are used, how does the train make and break the contact?	The rail bending under the train load causes mercury to make connexion, or break it, between the earthed casing and the conductor.	By bending the rail. (There is answer from Hungary.)
90. Do these electrical devices only serve to warn the signalman or do they lock levers?	In some cases, for warning only; but principally for releasing the levers and the other locking gear.	They chiefly are for locking and leasing the levers and locking of the cabins.
91. Have you also taken into consideration other devices for this purpose, or tried them already with success?	No (apart from the lever locks already mentioned).	As a rule, no. On the Austrian N Western and South-Northern sw control locks are used, dependin the mechanical and electrical r locking gear.
92. To what extent do you consider the introduction of such devices desirable and practically realizable, in cases of switches taken : *a*) From the facing side; *b*) From the trailing side?	*a*) The general opinion is that such devices are desirable for all switches taken by trains from the facing side. *b*) As a rule there is no need; only perhaps in those cases in which the switch cannot be seen well from the cabin and has to be operated (where there is a busy shunting service), immediately after it has been passed.	*a*) As a rule only for switches t from the facing side; partly als switches which can neither be centrally, nor locked. Partly als and (*b*) for those which can be centrally, but at a greater dist (about 250 metres [273 yards] and wards) from the cabin or cannot be seen from there.
93. Have these devices in any way given rise to any difficulties in the service or in their maintenance?	Not of any importance. They facilitate the service. They must be carefully kept up-to-date, but this presents no difficulties.	As a rule none worth mention On the Austrian North-Western South-Northern sometimes by cutting open of switches fitted control lock. In Hungary, none.
94. Which devices are you going to prefer when making new installations?	Treadles, rail contacts, also time locks when switches are only locked singly; electric route locking when several switches are locked for the passage of one train. Alsace-Lorraine also speaks in favour of insulated rails with rail contacts in connexion with the locking of levers.	As a rule treadles and insulated r according to the conditions. The Austrian Southern prefers, a ger stations where the block sy is used. electro-mechanical co treadle rails, at smaller sta pressure treadles, and at swi not otherwise protected Schi treadle rails. (The answer for Hungary is miss

C.

95-103 : *Graphic representation* of the occupation of the platform tracks at busy stations, and their use in case of any alterations in the service.

95. Have you, in order to facilitate the management of the traffic at busy stations, used graphic representations for showing the occupation of the tracks?	Yes, in a few districts. Partly there are only indicating plates (Wurtemberg, also coloured fields on the block apparatus together with the arrangement or the so called "occupation" interlocking or route interlocking (Bavaria. Baden). All these show if tracks are occupied.	As a rule, no. However there a use, in some cases, the diagram track representations (which ar stations) with movable buttons, w show in the case of arrivals, a that of departures that it is goi be free.

Summary of the answers. (Continued.)

switches taken from trailing side. ome cases of shunting rations, when the ches are at a greater ance from the cabin.	Chiefly for switches taken from the facing side, which cannot well be seen from the cabin.	Only in cases from the facing side; in mechanically-operated apparatus also, only in special cases.	*a*) For switches which must be thrown over immediately a train has passed. *b*) Such do not as a rule seem necessary.	(No answer from the Federal Railway.) The St. Gothard Railway thinks it advisable to have them in the case of switches which are not visible from the cabin and which are taken from the facing side by trains.
he time locks.	Not in the service. Difficulties in maintenance appear to occur particularly in the case of insulated rails.	None worth mentioning.	In the north of Sweden the treadle rails require careful and accurate supervision, when there is snow and ice. Therefore they are not suitable for such climatic conditions.	In the opinion of the St. Gothard Railway, time locks are not suitable in the case of stations where many shunting operations are carried out, as when this system is adopted too much time is lost.
ocking rails.	Sufficient experience is lacking.	Interlocked rails and time locks.	Sufficient experience is not available.	Uncertain.

C.

95-103 : *Graphic representation* of the occupation of the platform tracks at busy stations, and their use in case of any alterations in the service.

No.	No.	No.	No; but on the Swiss Federal Railway most of the cabins are equipped with automatic indicators showing the occupation of the tracks.

QUESTIONS.	Summary of the answers. (Continued.)	
	Germany.	Austria and Hungary.
96. In the case of these graphic representations, is the occupation of the tracks, according to the service, marked on them definitely, so that they only serve to facilitate a general view and make it easier to see the effect of any alterations?	Yes, except in the case of the devices with movable indicators mentioned under 95, in the case of Wurtemberg, Bavaria and Baden.	Graphic representations other those mentioned in the answe question 95 are not used.
97. Or are there movable marks, to indicate the occupation of the tracks, so that they can quickly be ajusted in accordance with the changing conditions as they are notified?	As a rule, no. There are exceptions in Wurtemberg, Bavaria and Baden See under 95.	As above.
98. Or are these marks moved simultaneously with the notifications received from ouside, either by the employees in charge or by the trains themselves?	No.	As above.
99. Or are these marks set by the traffic manager before the track is occupied, the setting serving as permission for the train movement in question?	No, unless the setting of these marks is in connexion with the system of blocks or, as in Wurtemberg, where indicating plates, as in Bavaria, where interlocked indicators are used and in Baden, for route interlocking (see 95).	As above.
100. Or are there any other relations between the graphic representations and the trains movements and the occupation of the tracks concerned?	As a rule not. In Bavaria and Baden, the devices mentioned above with the chief signalling or other cabin closes the entrance to a track which is occupied.	As above.
101. Does this representation of the occupation of the tracks also extend to shunting operations and to locomotives running light?	Only in solitary cases.	As above.
102. In this representation of the occupation of the tracks also extended to other than platform tracks? To what extent?	As a rule on all entrance and departure tracks, in so far as any representation exists.	As above.
103. Have such arrangements, and which, proved to be valuable as regards facilitating the service and as regards safety?	Yes, graphic representations have proved particularly valuable when special trains have to be intercalated. Similarly the indicating plates, the interlocked indicators and the route series have proved useful.	As above.

1-28 : Hand-operated apparatus.

Operation of switches.
Questions 1, 3, 10, 5, 11, 8, 6, 9, 7, 16, 2.

The experience of half a century, on which the design of the newer hand-operated apparatus is based, has it is true resulted in a desirable comprehension of some of the questions involved in the design, and have led to more or less uniform practice; but on some important points opinions still differ very much. In the first place here is the question, whether switches at a distance are to be operated by means of rodding or by a double-wire transmission (1) [1]. During the last twenty years, wire transmission has become materially extended in the countries this report is dealing with. Germany has adopted double-wire transmission for the operation of switches in the large majority of cases, and Austria-Hungary has adopted it exclusively. Similarly in Denmark, Russia and Sweden, when new installations are in question, double-wire transmission is almost the only system adopted. On the other hand, rod transmission is preferred by the Alsace-Lorraine State Railway, the Baden State Railway, the Rumanian State Railway, the Ssysran-Wjasma Railway and the Swiss railways. The decision of the question, which system of transmission is the best, is not one which is within the scope of this report. It may, however, be pointed out that the chief disadvantage of rod transmission (giving no indication at the station if the continuity of the rodding is interrupted) is only of practical importance in exceedingly rare cases; and that on the other hand, the risk of fracture of the wire, and the defects of the appliances designed to make this harmless have not, in the many applications of this double-wire transmission made, proved so serious that it has been necessary to consider this system of transmission (which is advantageous from many points of view) as unsuitable or even as less suitable.

The new and decided position recently taken by some administrations in favour of rod transmission, has drawn fresh attention to this question; so also has the favourable verdict of the Bruchsal Works, who are very important manufacturers of signalling apparatus. The interest in consequence taken in the subject can be but an advantage from the general point of view. More especially does it have the effect that those in favour of wire transmission are not content with leaving matters as they are, but are observing and testing the reliability of the automatic safety appliances (to act if a wire breaks) under the most varying conditions, and are striving to obtain by stricter supervision and more careful maintenance the results which it is not yet possible to obtain by improved design. In the case of wire-transmission equipments, there are many great technical differences, which show that there is ample scope for the work of designers. In Germany, equipments with stretchers and cuttable switch locks, for the points separately, are most usual; while in Austria-Hungary there are generally no stretchers, but bolts for both points

[1] The numbers inserted in the text in brackets represent the index numbers of the questions which are being considered.

simultaneously, with shearable pins at these bolts. In the former country, wire ropes are generally used at the deviation blocks; in the latter, chains are preferred. It cannot be denied that the wire ropes at the deviation blocks form parts more liable to fracture than the wire transmission proper, on the guide blocks. There is a risk of fracture, after a few years of use, even in the case of the best wire ropes. According to the tests made by the Saxon State Railway, a good steel-wire rope having an effective cross-section of 9·6 square millimetres (189,460 circular mils), with the wires laid around a hemp core, can stand about 50,000 to 120,000 forward and backward movements, when forming an S shaped curve round two deviation blocks and subjected during the test to a tensile force of 150 kilograms 330 lb.).

It is intended in future to use an effective cross-section of 9 square millimetres (177,600 circular mils) and to specify that the rope must stand 100,000 forward and backward movements.

The signalling system of the Saxon State Railway has experienced, between 1 January 1908 and 1 April 1909 (1), the following fractures of wire transmission operating switches and signals :

2,875 switches with wire transmission : no true wire fractures, but 64 fractures of wire ropes;

3,688 signals with wire transmission : 3 fractures of wires and 103 fractures of wire ropes;

603 switches with rodding : 2 fractures of rodding and 1 fracture of a crank.

In the cases of the wire and wire-rope fractures which occurred, four signals remained in the position " line clear " and at one switch the lock did not act. That the signals did not automatically fly to danger, was caused in two cases by snow which had accumulated, and one case by the sticking of a soldered part, and in one case by the fact that part of the wooden protective casing interfered with the free movement of the counterweight. That one of the switch locks failed was also caused by the sticking of a soldered part; thus this was a fault in the construction, for if the dimensions of the different parts had been properly proportioned, this could not have occurred. Now although in consequence of the automatically-acting safety appliances, the fractures of wire ropes only result in a dangerous state of affairs in the rarest cases, yet the number of fractures is by no means negligible. It would no doubt be still further reduced if the ropes were renewed in good time, as soon as the signs of wear became apparent. In some districts, very good results have been obtained in this way. As the above statements show, one great enemy of wire transmissions is snow and ice formation; this not only impedes the movement of the transmission proper, but also that of the signal, switches, etc., and may prevent the appliance which is being operated from assuming its proper end position.

Most of the administrations therefore justly attach much importance to protective

(1) The weather conditions during the 1908-1909 winter were particularly unfavourable.

casings of the switch gear, and to careful drainage of the ground under the transmitting and the operating gear (24), and no doubt further improvements can still be made in this direction.

In comparing rod and wire transmissions, we also have to consider what necessity there is for any special locking gear on switches operated by the one or the other transmission. We find no great difference in this respect. The managements who prefer rodding in Germany (Alsace-Lorraine and Baden) think it very extensively necessary, in the case of rod transmission, to have separate locking gear in addition to the usual point lock (3). All the switches taken from the facing side, on the Alsace-Lorraine Railway, have such separate locking gear; in Baden, all the switches taken from the facing side by passenger trains, if they are at a greater distance than 300 metres (328 yards) from the cabin and are run over by arriving trains or by trains running through. Rumania, which has also decided in favour of rodding, only uses special locking gear exceptionally, in the case of switches taken from the facing side and situated on curves. On the other hand, Switzerland has special locking gear in the case of switches, operated by rod transmissions, taken from the facing side, on the main line, if they are more than 150 metres (164 yards) from the cabin (this working gear is in connexion with the wire transmissions operating the signals), and also in that of switches which are more than 400 metres (437 yards) from the cabin. The switches taken from the facing side and operated by wire transmissions (10), are protected to about the same extent by the administrations which have adopted wire ropes as their chief means of transmission. In Prussia, all the switches taken from the facing side, which are run over by fast trains, are fitted with control bolts. The only exceptions to this rule are, under certain conditions, switches located near the station platforms. In Austria the same protection is adopted in the case of switches taken from the facing side by passenger trains. On the Russian railways, this is done in a limited number of cases only. This tends to show that the practical experience of many years indicates that there is approximately the same safety, whether rodding or wire is used for operating the switches.

If we also take into consideration that those who are exclusively in favour of rodding for the operation of switches employ almost always wire transmissions for operating the signals, and that the importance of the proper position of the signals is just as great as that of the proper position of the switches, we may conclude with certainty that wire-transmission methods will continually be improved, and switch operation by this method will consequently improve, and existing imperfections will be eliminated more and more. It is true that the question of operating signals by means of rod transmissions has also been considered; but the greater distances involved in these cases makes the matter rather hopeless. As a substitute, the Bruchsal Works have proposed a combination : rod transmissions for operating switches and electric operation of signals. Such a mixed installation is at present in use in Germany on the State Railway at Colmar.

As most of the more important switches operated by rod transmissions have control bolts fitted, this has made it unnecessary to equip them with an electric control of the switch (5) to show if anything is wrong (failure of the transmission, points not home). In Saxony such an electric control was used for a considerable number of years with success, before switches were equipped with the now-usual cuttable switch lock. This control fell into disuse when the newer point locks were introduced.

The use of cuttable locks with separate movement of the points has become very general, and is very generally recommended. But opinions vary as to whether it is better to do the locking (8) by clamping the blade and the stock rail together, as in the hook locks, or by exerting a thrust against the blade from a special point of support, as in the articulated locks. In Germany as a rule, locks with a clamping action are preferred, although there are also many cases where articulated locks with special points of support are used. Russia, Rumania, Denmark, Sweden and Switzerland, pronounce in favour of the system of exerting a thrust against the blade from a special point of support. Austria-Hungary in this respect takes up a special position 6, as here as a rule, Siemens switch bolts are used, which make it impossible to cut open the switch without destroying part of the lock; shearable pins are provided for the purpose. When a switch is cut open in this way, there is no reaction at the cabin; but a locking action comes into play at the bolt, and prevents its movement, after the switch has been cut open. The Breitfeld and Danek cuttable switch lock, which reacts on the cabin, is only used to a limited extent. Except in the case of the Aussig-Teplitz Railway, which uses the Schnabel and Henning device, locks acting when a wire breaks are as a rule not used; it is true that the Austrian administrations draw attention to the fact that the fracture of a wire transmission is very rare, and in some cases has never yet happened; this is probably the result of the nearly exclusive use of chains at the deviation sheaves.

In Germany, Rumania and Russia, favourable results have been obtained with devices for holding the switch in its end position if the wire breaks and for locking the operating lever at the same time (9). One would not like to do without them. Denmark, Sweden and Switzerland have not yet enough experience available to come to a final conclusion on the point.

When the cutting open of a switch breaks the connexion between the operating lever and the swith gear, this has given rise to the fear (7) that it would be possible that a switch (when a route has been made) should be, wrongly, disconnected from the operating lever and then operated with the lever provided for making the connexion. Practice has shown that this need not be taken into consideration. It is generally thought that the only thing necessary is to place the connexion under a lead seal and also to lead-seal the connecting lever. The principle silently observed in the case of many safety appliances here also comes into play, namely, that it is necessary to be protected against the consequences of a mistake, but not to be protected against every possible criminal action of an evil-minded employee.

One special form of wire transmission for switches from which much was expected formerly, was operation with three different positions of the lever (16); in the middle position, the lever releases the switch so that it could be operated locally. This has only been introduced to a very limited extent, except in Sweden. It is only used in a few cases in Baden, on the Moscow-Windau Railway, and on the Swiss Federal Railway, but in Sweden it is used fairly extensively.

Locking of switches.

Questions 12, 14, 15, 13.

Then also the device, from which the wire transmission system of operating switches has developed, the switch bolting (12), is only applied to a very limited extent, except as regards the control locking of distant switches. Only in Denmark are such locking devices frequently used. In Rumania there are none. In other countries, they are used either as provisional safety appliances or in cases where the traffic conditions are particularly simple. The locking devices are as a rule not cuttable (14). Only in Russia are shearable pins used for the locking bars; and on the Stockholm-Rimbo Railway the cutting open of a locked switch disconnects the wire transmission of the cabin.

Arrangements for keeping locked switches in their end position if the wire breaks (15) are stated by some to be desirable; but in most cases they are not considered necessary. There are even important reasons against it, for then if when the wire has broken the switch is locked in the end position, the switch can no longer be operated by hand, after the object of the locking has been attained, and it may be absolutely a necessity, for traffic purposes, to operate the switch. But it is an advantage if the fracture of a wire prevents the operation of the levers in the cabin; and most installations are so arranged.

A matter of importance is the distance up to which switch locking can be considered reliable (13). For it represents, at the same time, the limit of the distance at which switches can be operated, special switch locking being also used. This largest locking-distance is as a rule 500 to 600 metres (547 to 656 yards), with a wire travel of 500 millimetres (1 ft. 7 $^{11}/_{16}$ in). It is true that distances of 800 metres (875 yards) (Swiss Federal Railway) and 1,350 metres (1,475 yards) (Alsace-Lorraine State Railway) are also mentioned, which materially exceed the usual limits of switch operation.

Operation of signals.

Questions 17, 18, 19, 23, 24, 25, 26, 20, 21.

In the case of signalling operations, double-wire transmissions have everywhere replaced single-wire transmissions (17). The latter are no longer used by any of the railways we are dealing with. The distance (18) up to which, on approximately straight sections, double-wire transmissions are considered safe for the proper operation of signals, is stated to be 1,000 to 1,500 metres (1,094 to 1,640 yards), the travel of the wire then being usually 500 millimetres (1 ft. 7 $^{11}/_{16}$ in.) (19). Some administrations however reduce this, according to distance of signal; on the Austrian State Railway it is reduced to 250 millimetres (9 $^{13}/_{16}$ inches).

In the case of signals, just as in that of switches, we have also to note an impor-

tant difference as regards the use of stretchers (23). In Austria and Hungary, stretchers are hardly used at all. In Denmark also, new constructions are made without stretchers. But in the case of the other administrations, the absence of stretchers is the exception, and is as a rule only found when the distance of operation is less than 200 metres (219 yards). The safety action of the stretcher, setting the signal to "danger" when the transmission breaks, must be replaced in the absence of stretchers by a release which if one side of the double-wire transmission becomes slack allows the counterweight of the signal arm to move it into the "danger" position. The advantages of a uniform initial tension and of the strong pull exercised by the gravity stretchers when a wire breaks, are evident. They are however counterbalanced by the disadvantage that the corresponding device has to be inserted in the transmission, and that everything depends on the proper working of this device; not only has it to be protected against the deleterious action of ice and snow (24), but also against illicit interference (22.; for it makes it possible, when the weight is raised (whether direct from the cabin or by pulling the wire), to change the position of the signal without operating the lever.

Then also the system of ensuring that the signal remains in the "danger" position or is moved into the "danger" position by the weight, in the case the wire breaks (25), cannot be considered as wholly unobjectionable, if when a wire breaks a signal already standing at "danger" can temporarily assume the "line clear" position before it once more finally resumes the "danger" position.

A question of particular importance is whether it is advisable to use the signal wire transmission also for opening switch locks (26). That it is not an advantage as regards the operation of the signal, if the wire transmission is a long one, is beyond doubt. Observations have been made showing that the automatic movement of the signal to the "danger" position when a wire breaks can be prevented by such an arrangement; however, generally speaking, no unfavourable results have been obtained with the newer bolting devices, which offer but little resistance. The use of differential locking in the case of intermediate locking has proved very satisfactory, and there are several good designs. Austria-Hungary and Rumania however, do not intercalate such intermediate locking. In Russia it is used very rarely. In other cases, it is not excluded, but it is in cases observed that it is only used to a limited extend.

The same applies to the combinations of the distant-signal transmission with that of the main signal (20), which can affect the efficiency of the wire-breaking safety gear, and under certain conditions even the ordinary operation of the signals. Austria-Hungary and Saxony have therefore adopted it as a principle to have separate transmissions and levers for the distant signals and the main signals, the levers being of course interlocked. The same arrangement exists also to some extent in Russia and Denmark also. But in the other cases distant and main signals are nearly always operated by one lever and by one wire transmission, which is in cases divided at the main signal.

A method of operating main and distant signals, one common wire transmission being used, but developed in quite a different way, has been made possible by the use of electric interlocking (21) in those cases in which the distant signal of a main signal is immediately next to the preceding main signal, or can be erected together with it, for instance when a starting, distant signal is at the entrance signal. It is then not usual to operate both with one wire transmission; but the distant signal is electrically interlocked, so that the circuit can only be closed when the corresponding starting signal is set to " line clear ". This method of operation is also adopted when several signal arms are to be operated by one and the same lever. Otherwise the electric signal interlocking (interlocking of arms, arm flying to " danger " position) is naturally the means adopted for making the train act on the signal and make compulsory the operation of the block system and the signals, thus in the case of starting signals of block sections and other similar cases. The electric interlocking of signals, which at first was only applied with hesitation in the case of hand-operated apparatus, now forms a recognized important and reliable addition to it, and is also beginning to be introduced in the cases in which the mechanical control at greater distances is not by itself considered reliable under all conditions.

Ball and roller bearings.

Question 4.

It is remarkable that ball bearings and roller bearings (4) are as yet but little used on switching gear and more especially on transmissions and distant apparatus, although good results have been obtained with several experimental installations. Only for switch rodding are roller bearings used to any considerable extent. But the fact that in the case of long transmissions it is very desirable that there should be easy operation and action of the automatic safety appliances might form an inducement to pay more attention to ball and roller bearings. It may, therefore, be assumed, that such devices will be used more and more.

Size of frames.

Question 27.

The size of the apparatus which is hand operated (27), is as regards the number of levers, within moderate limits. The greatest size is represented by cabins with 70, 80 or 90 levers; and this no doubt is due to the large amount of space required for such apparatus as well as to the difficulty of operating larger installations.

Improvement of apparatus.

Question 28.

Important improvements in hand-operated apparatus (28) are not in prospect for the moment. However, there is no doubt that further improvements will be made in the combination of electrical and mechanical devices, and it is to be expected that in this way many difficulties, which at present have arisen in the case of purely-mechanical treatment, will be overcome very satisfactorily. Thus the question of safety in the case of the fracture of a wire, is one which is very probably solvable by electrical methods. Then also it may be expected that the development of power-operated installations will stimulate, in more than one direction, the design of hand-operated installations; for at present there is no question of replacing hand operation by power operation in the majority of cases, and attempts will be made to

adapt part of the improvements in power operation also in the case of hand-operated installations.

29-47 : Power operation.

System.

Questions 29, 30.

Power-operated installations (29), within the scope of our report, are nearly entirely limited to electrically-operated and pneumatically-operated installations. On one railway only, in Russia (Weichsel Railway) are there installations operated by liquid under pressure. The most important ones are the electrically-operated installations, the quick development of which is due to the activity of Messrs. Siemens & Halske of Berlin and Vienna, and of Messrs. Jüdel & Co. of Brunswick; in Germany, there are 243 installations, 6,907 switches and 1,824 signals, electrically operated, either in use or being installed; in Austria-Hungary, 22 with 411 switches and 224 signals; in Denmark, 8 with 77 switches and 7 signals; in Russia, 3 with 40 switches and 9 signals. On the Prinz-Heinrich Railway in Luxemburg there are several electricallyoperated installations constructed by the Taylor Signal Company of Buffalo. Taking it altogether, this is already a very important application of electric operation. Among other power-operated installations, there are in Germany 10 electropneumatic installations with 1,135 levers constructed by the firm C. Stahmer of Georgsmarienhütte, and then there are also several administrations in Germany and Russia who have some individual signals operated by compressed carbonic acid, controlled electrically.

Moving of switches.

Questions 31, 33, 34, 35, 37, 36, 32.

The power in the case of electrically-operated installations (30) is nearly always supplied by continuous-current motors, but in Prussia solenoids are also used, in some cases, for signals. In the newer installations, matters are always arranged (31) so that the switch can always be moved, forwards or backwards, whatever its position, and so that after it has been cut open (33), it can be put again into normal condition without anything special having to be done at the switch itself. The electric control of the proper position of the switch (34) is generally such that it checks the correct position of each of the two blades. In some cases however, only the whole operation is checked.

The simultaneous operation of several switches (35) is generally limited to the number "two". As a rule these are related switches; when these are acted on by the one common lever, there is however this difference that the movement of the two switches is not in all cases effected simultaneously, by switching in the motors in parallel, but that in some cases the two motors are arranged so that the one motor first throws over the one switch, and that when this operation is completed, the current is automatically switched on to the other motor, which then begins to throw over the other switch. Prussia prefers the latter arrangement, for if the first switch fails (37), the second remains in its original position. In Austria, good results have been obtained with the two motors connected in parallel. On the whole (36), separate operation of the switches is by far the most general, as this makes

the arrangement of the conductors easy, and also eliminates the disadvantage that if in the case of shunting operations several switches are moved simultaneously, the attention of the operators is as a rule only fixed on one, and that another at the same time can have been moved prematurely. The time required for throwing over an electrically-operated switch (32) is stated to be two and three seconds, and for a pneumatically-operated one, two to eight seconds; the longer periods in the latter case seem to apply to exceptional cases, in which specially-long transmissions were in question. On the average, the time required for pneumatic operation is probably but little longer than for electric operation. The time required when a fluid under pressure is used is stated the three seconds.

Maintenance Failures.

Questions 44, 41, 43, 42.

In order to look after and maintain the power-operated installations (44), specially-equipped mechanics are nearly always considered necessary; if possible they receive the necessary practical training when the installation is constructed.

It is true that up to the present, the number of failures has been rather frequent in the case of power-operated installations (44), although the failures have as a rule not been important. In Germany, where there are already a very considerable number of power-operated installations in existence, there are as a rule more failures than in the case of hand operation. The same observations has been made in Denmark. In Austria-Hungary and on the Russian State Railway, however, power-operation has on the whole shown probably rather more favourable, certainly not less favourable results than hand-operation.

The installations with liquid under pressure, on the Weichsel Railway, receive a less favourable verdict. Not only have there been more failures than in the case of hand operation, but it has also taken more time to remedy them. On the other hand, in the case of electrical operation (43), failures have in nearly all cases taken a shorter time to make good than in the case of hand-operation. The causes of the failures were very varied (42): contacts not properly closed, the loosening of binding screws, faults in the cables, defective motors, the blowing of fuses in consequence of external resistance to the movement, absence of the check of the position of the blade in consequence of the presence of foreign bodies or movement of the track, defects in the insulated rails, etc. At first sight, this seems rather serious, but it must not be overlooked that a considerable number of these failures result from irregularities in the track and the switches, and that these electric installations in this way form an excellent check on the proper condition of the track, wich on the whole cannot be undesirable. The electro-pneumatic installations are perhaps rather less sensitive; Prussia states in this connexion, that the only cause of failures was the leaking of the operating piston.

Advantages.

Questions 40, 38. 39.

A saving in the staff, in the case of power operation (40), is not everywhere effected, but as a rule there may probably be a saving of 20 to 33 per cent, as Alsace-Lorraine, Wurtemberg, Hungary and the Russian State Railway recognize.

Prussia states that it depends on local conditions, whether and what saving in the staff can be effected.

Accordingly opinions also differ, as to what economical advantages there are (38). These are also affected by the occasionally high cost of maintenance, and by the interest charges of the considerable outlay required; the general experience up to date does not show that these are so marked as to form a strong argument in favourof the future extension of power operation. In Austria-Hungary however, economic advantages have resulted both as regards staff and as regards maintenance.

The question of the economic advantages is however in this case also not the only deciding one; the most important point at places with much traffic is to have such arrangements that the staff can, without being overworked, work the service smoothly, quickly and safely (39). All the administrations which have up to the present used power installations agree that they make it easier to work the service; this is a sufficiently-great advantage to make it certain that power installations will be used in future, in spite of sundry existing minor defects. Therefore those administrations also, who have already tried power installations in cases of much traffic, consider the further extension of power operation in the case of installations at large stations (47), particularly as there is no doubt that progress will be made and such devices will become more and more reliable. Electric operation by motors in such cases receives much more attention than other systems. The administration of the Prussian State Railway, which alone has a considerable number of experimental electro-pneumatic installations in use, states that the comparative trials are not yet completed.

Future applications. Question 47.

Any suggestions for the improvement of power installations (46) are not made, except as regards some minor constructive details; this is very natural, for the administrations are at present engaged in testing and adapting the existing appliances, which are the result of the excellent and ingenious work of inventors. It must however be mentioned that a certain difficulty arises from the fact that the electrical installations require continuous current, while single or polyphase currents are available at so many places. The desire expressed by Saxony, that it should also be possible to use alternating-current motors, therefore does not seem unjustified.

Improvements. Question 46.

Now although there seem to be fundamental differences between installations operated by hand and by power, keeping them quite distinct, there are nevertheless signs that intermediate forms may become evolved. When carbonic acid is used, it is already possible to carry out certain operations in connexion with hand-operated installations as power operations, by using compressed gas and an electric control. The more recent installations of this kind (45) for individual signals which are a long way off, have given good results. Just as well is it possible, where suitable current is available, to carry out individual operations by electric

Individual power appliances. Mixed operation. Question 45.

power and so to relieve mechanically-operated installations in cases where it may be necessary to operate at greater distances than they can be depended on. As stated above, this has already been done on a large scale; at Colmar (Alsace) there is a cabin equipped for the electric operation of signals, with a rod transmission for the switches; this a given satisfactory results for several years now, and appears to act as stimulus to other similar applications.

If to make the work of the signalman easier is the only question involved, the arrangement might be considered of equipping installations operating signals at a distance with power-driven gear, to be set in motion as required, the actual work of operation being done by a small motor. Trials of this kind were formerly made by the Saxon State Railway, but did not lead to any result.

48-65 : Signals and switches generally.

Signals.

Questions 48, 49, 51, 50, 52, 53, 54.

Among the devices which are found both in the case of hand operation and in that of power operation, we may in the first place mention those for ensuring that the signal is in its proper position. The electric checking of the " line clear " and " danger " positions (48 and 49) is applied in the case of all power installations, but in that of hand installations only to a very varying extent. Only some the administrations consider these checking devices indispensable for whole classes of signals, especially entrance signals. Among them are the Alsace-Lorraine State Railway, the Hungarian State Railway, the Austrian North Western and South Northern, and the Swiss railways. In other cases, the degree of visibility of the signals, the length of the wire transmission, and any existing interlocking of the signal levers with any other appliance are the deciding factors, whether an electric check of the position of the signal is to be considered necessary or not. The check as a rule only exists in the case of main signals, and that for both the positions " line clear " and " danger ". The Swiss Federal Railway is of late also checking the intermediate position; in which the meaning of the signal is doubtful. On the other hand, some of the railways only check the " danger " position, as this is the most important from the point of view of safety, and that in such a way that in case the check does not show the signal at " danger " the corresponding part of the line has to be considered unprotected. The check is not as a rule applied to caution or slowing signals or their positions. Moreover, except in the cases of signals operated by power installations, the signal-control current is not utilized for locking or unlocking parts of the mechanism (51). But it seems worth while, taking into consideration the possibilities of failure which exist in the case of long wire transmissions, particularly if they include some locking gear or also have to operate several signals, to consider whether the electric control of signals should not be adopted generally, and whether the absence of the indication that the signal is standing at " danger " should not have the same locking action at the cabin as if the signal lever had not been thrown over. It seems also advisable to extend this

electric control of the signal to the distant signals, which in practice are at least as important as the main sigals.

An electric check to show that the signal lanterns are alight (50) is generally dispensed with; it also does not appear to be taken into consideration for the future, to judge from the results obtained. Only in cases where electric signal lights are used (tunnel signals in Switzerland; a few signal lights on the Russian State Railway and a switch section signal in Saxony), is a check provided by a control lamp in the same circuit.

The ordinary illuminating power of the signal lanterns as a rule appears to suffice (52 and 53). Attempts to improve the illuminating power have only been made in Baden (by increasing the size of the reflectors), in Saxony (by unsymmetrical arrangement of the reflectors for the front and back light), and on the St. Gothard Railway (by increasing the size of the burners). Electric lighting has been applied to a number of signals with considerable success. Trials of acetylene lighting did not give satisfactory results.

In some districts, liable to fog, the effect of the signals is reinforced by repeating the lights at definite intervals. A yellow double light has been introduced in Germany since 1901 on several large experimental sections (extending altogether to over 200 kilometres [124 miles]), as a "caution" distant signal; this light shows up much better than the other coloured lights because the amber-yellow glass absorbs very little light. It will probably be introduced in the whole of Germany for distant signals. The yellow distant signals are also used in Denmark.

All administrations are striving to prevent the fracture of the signal-light glasses (54). The chief measures adopted are wire glass, as well as an elastic setting or one which gives a little, such as tin, leather, lead, etc. It is also important to reduce any shock resulting from the impact of the mass of the signal; counterweights and spring stops are used for the purpose. Some administrations consider wire glass very useful; in other cases (Swiss Federal Railway), it is considered unsatisfactory. It is true that it cannot readily break into pieces, but it easily becomes cracked and crumbles, so that part of the white light passes through.

Switches.

Questions 55, 56, 57.

The possibility of the hand-operation of switches on the spot, in cases of failure (55), is everywhere provided for; in the case of electric motors frequently only by the provision of an auxiliary cranked handle; in this case, the operation takes a comparatively-long time. In the case of hand and power operation, the lever which is there ready, is fitted into the gear and connected with the switch without difficulty. On the Saxon State Railway, the hand levers are left permanently in place, and as a rule they are only kept disconnected.

Particular conditions exist in districts where spring switches are used (56); the blades of these switches can only be moved into the other position by overcoming their elastic force, which is not inconsiderable. This elastic force amounts to about 50 kilograms (110 lb.), and acts at the blade not in contact in the direction

opposed to the movement produced when the switch is cut open. Thus theoretically it is to some extent in contradiction with the cuttableness of the switch. As, however, this force of 50 kilograms (110 lb.) only comes into play to a materially smaller extent and as on the other hand the forcing open of the lever interlocking in the cabin, when the switch is cut open, requires a force of about 200 kilograms (440 lb.) acting on the transmitting parts, there remains in the case of spring switches an ample margin of resistance against the cutting open. Nevertheless, provision is made in the case of electric operation (57) to increase the resistance to movement of the blades in their final position by adding a spring friction catch, so that from this point of view there is nothing against extending the use of spring switches. In the case of compressed-air operation, no particular devices at spring switches are necessary, as the pressure behind the piston overcomes the resistance of the blade readily. Up till now, within the limits of the countries we are considering, it is only in Germany and Austria-Hungary that spring switches set from a distance are used, in most cases experimentally. It is, however, to be expected that their use will become extended, as they present advantages not only from the point of view of smooth running, but also from that of maintenance, and prevent any longitudinal movement of the blade relatively to the stock rail; and this is particularly desirable when points with the blade and stock rail clamped together ase used.

Inclusion of barriers and gates.

Question 58.

Besides signals and switches, barriers and level-crossing gates are also frequently operated from the cabins (59). Both can be included in the route interlocking, so that the corresponding signal cannot be set to " line clear " until they are in the proper position for that purpose. But nearly everywhere, only the barriers have been included, while the level-crossing gates are only operated from the cabin, but not interlocked with the route mechanism, in order not to stop the street traffic the whole time the block continues. This relief to the street traffic, however, results in increased responsibility for the signalman. The uniform practice of the majority of the administrations shows that this is, however, considered the lesser disadvantage.

Action of trains on cabin.

Question 62.

A material improvement in the value of the safety appliances has been effected by making the train co-operate (62). This makes it possible, by the use of treadles and rail contacts, to make any operations in the cabin dependent on the condition that the train has passed a given spot or has left a given section of road. This is effected by having electric block fields in the signal bex, or by electric interlocking with the signals, unlocked by the train; the latter is more particularly the case at the beginning of block sections. Devices of this sort have been very largely introduced not only in the case of power operation, but also that of hand operation.

It is true that rail contacts are also used to notify the approach of a train, but only in a few solitary cases.

One of the most important questions in railway working has always been, how

cases of the over-running of signals can be prevented, reduced or made harmless. Distant signals and detonators give valuable results in this connexion, but they cannot absolutely prevent the men on the locomotive from overrunning a signal if there is thick weather, if the signal light has become extinguished, or if any occurence strongly attracts their attention. Detonators, if powerful, are bound to be noticed by the driver even under unfavourable conditions; as a rule, they are used only in cases of fog or if a section has unexpectedly to be blocked, and thus in many cases the possibility of the danger mentioned continues to exist. Consequently in some cases, alarms or gongs have been added in the distant signals; these continue to sound, when the train passes, if the signal is set at " danger ". But it has also been considered desirable to have some means of drawing attention to the spot where the distant signal is located, without putting an extra load on its wire transmission by a second device which has to be operated. Among such are, besides the strengthening of the illuminating power of the signals lights and having several lights, as already mentioned, also the large marks at the distant signals, made of sleepers and used in Prussia, and the sound-reflecting walls, now being tried, which are to attract the attention of the locomotive driver by reflecting the noise made by the trains, as in passing under bridges. Electric and pneumatic horns which are automatically started by the trains, have also been tried at distant signals for the same purpose. These devices have not, however, been introduced to any large extent, and have mostly not passed the stage of long experimental trials, except in the case of the large marks at the distant signals, which are very satisfactory in a limited way, but cannot be considered to be a very powerfully-acting accessory.

Prevention of over-running of signals.

Question 59.

Then also many inventors have for tens of years aimed at making a warning signal appear or sound in the locomotive cab (59) when the train approaches a main signal standing at " danger ". But only few of the devices proposed have proved at all promising. In the countries we are considering, matters in this respect have as yet only reached the experimental stage. The chief difficulty is that the electric-contact devices for conducting the current from the line to the locomotive (such as the Lartigue " crocodile " contacts) cannot be depended on to act satisfactorily under unfavourable climatic conditions, as extended trials made by the Saxon State Railway on a line in the Erzgebirge have shown; and that mechanical devices are not only very liable to destruction in consequence of the high speed of trains, but also exercise a bad influence on the reliable working of the distant signal, if connected with it. Nevertheless, several experiments have recently been begun in Germany with the van Braam signalling system, in which a treadle on the line acting on a sensitive lever with a transmission to the cab, fitted to the locomotive, operates a powerful signal, records the operation and if required also applies the continuous brakes. The latter seems at first sight a desirable action from the point of view of safety; but weighty objections have been raised against it.

Attempts are also made to obtain a certain amount of protection against the over-running of signals by having every case of over-running, even if it has not been

attended by any detrimental consequences, recorded by an automatic recording gear; and afterwards the driver is afterwards held responsible. This is effected on different stations in Prussia by a recording counter fixed in the office of the traffic manager, which is operated by means of a rail contact each time a signal is over-run. At the same time an alarm is released, which draws attention to each individual instance, so that these can then be properly recorded in a book.

Catching of trains.

Question 61.

The extreme measure to meet danger from the over-running of signals (61) is to turn the train into a side track, on which the train can run itself out or is stopped by sand (Köpcke's sand tracks); this is adopted by several administrations, in suitable places. On the other hand, on dead-ended tracks where only a small distance is available for the braking, sand is placed with hydraulic buffer stops at the end, in order to stop a train should it have come in too quickly. As a result of extended experiment, Saxony is lately considering the use of skids, which oppose to the pushing action of a train a considerable frictional resistance, reinforced by springs, designed for a length of stop of about 30 metres (33 yards).

Audible signal for trains which must stop at the entrance signal.

Question 60.

A special system of signalling has in a few cases become developed at advanced entrance signals, at which trains have sometimes to wait a long time. The German regulations specify that in this case the locomotive driver should receive the order "wait" (60). If this order cannot be given by an employee by means of a horn signal, an electric trumpet or syren is successfully used; this is placed near the entrance signal and operated from the station and signals "wait" by the Morse code, a series of short and long sounds being given.

Co-operation of traffic manager in setting to "line clear".

Question 63.

The setting of a signal to "line clear" is nearly generally made dependent on the co-operation of the traffic manager (63), by means of electric, or more rarely of mechanical unblocking devices, or by means of contacts which have to be made before the signal can be operated.

Indicators for shunting services.

Question 64.

Very good results have been given, in the case of a shunting service, in order to communicate between the top of the inclines and the switches at the corresponding sorting sidings (64), by loud-speaking telephones as well as by electric track indicators, which are constructed on the pattern of needle telegraphs. Track indicators which have incandescent lamps lighting up behind transparent number plates have also been used with advantage.

Mechanical needle instruments with a wire transmission have also been used instead of the electrical instruments. In many cases however, for instance in Switzerland, the siding numbers are only written on the buffers of the descending wagons; in Bavaria, numbered plates are hung on the buffers.

Newer installations and arrangements are devised with the object of making it unnecessary to given individual indications in the case of each descending wagon as

in accordance with American practice the order of sequence of the different sidings on to which the wagons are to run is laid down in advance in writing, so that the switches can be set in succession in accordance with this list. A further step in advance is the use of power installations to carry out the sorting operations required; in the system devised by Messrs. Siemens & Halske a paper band, perforated to correspond to the list, regulates the sorting automatically.

Any further improvements in connexion with switching and signalling appliances (65) are not contemplated by the different administrations. *Improvements* Question 65

In connexion with this discussion of switching and signalling appliances, we would mention a system intended, where traffic conditions are simple and where expenditure is to be avoided, to serve to some extent as a substitute for the necessary mechanical or electrical relation between the position of the signals, the position of the switches and the running of the trains. *Phono-indicator.*

The Russian Polessia State Railway has installed at seven of its stations an electric system for the control of the signals and switches, devised by its telegraph superintendent Oberst von Fiedler and called "Phono-Indicator". This enables the official controlling the traffic to send orders to the switchmen and the signalman to set the switches and the signals for a train, and also to see at any given moment in what position the switches and signals are.

While the switch is being operated, a trembling bell continues to sound until the switch blade is right home. A similar bell at once attracts the attention of the man in charge if by mistake he sets an entrance signal to "line clear" when the corresponding switches are in a wrong position.

This warning signal also sounds if two incompatible signal operations care carried out simultaneously.

The chief constituent part of the arrangement is an accurately-working switch contact, not affected by the weather. Any faults in the circuit are automatically announced by the bell. In addition to the electric ordering and controlling apparatus there is also telephonic communication between the station official and the switchman.

An extended controlling system, the centralized phono-indicator, has been developed for stations with more than three tracks; this is designed so as to satisfy all the requirements of a good centralized installation, with the sole exception of the interdependence produced by interlocking.

It is quite intelligible that with such a centralized system of control the safety conditions at a station where the switches and signals are operated singly by hand can be materially improved. The inventor himself however by no means proposes this as a full substitute for interlocking installations, but recognizes that these, if dependent also on the official managing the traffic, give the best security against the making of any mistakes.

66-77 : Electric interlocking of route levers.

Mechanical and electrical interlocking.

Questions 66, 67.

The interlocking of route levers (66) is nearly always effected electrically.

Wurtemberg and Switzerland however only use electrical interlocking rarely and chiefly apply mechanical interlocking. In Bavaria also this interlocking is applied in the case of station blocks. The Ssysran-Wjasma Railway has only mechanical route lever interlocking.

In the cases where route levers set to " line clear " are interlocked, the route is often also set by mechanical locking, without any intervention of the electric current in the first place, while an electric current is used for clearing. Continuous-current solenoids are generally used for locking.

Rumania and Denmark use this interlocking exclusively, with mechanic allocking and electric clearing.

Interlocking is everywhere recognized necessary in the case of entrance-route levers.

But departure-route levers are to a great extent interlocked in the same way (67). The existing exceptions are to be found where sections without block apparatus begin.

Interlocking by signalman. Automatic interlocking.

Question 68.

The system very generally adopted is that the interlocking of a route is effected by the signalman by a separate operation (68), an electric current being used; this system owes its adoption to the extensive use of the Siemens & Halske block apparatus. On the other hand, automatic locking when the lever is thrown over is also used in many cases. It has given satisfactory results not only in the case of power-operation, but has also been favourably mentioned in connexion with hand-operation.

In all cases where it is necessary to make certain that the switch is not movable while the train passes and the signalman has consequently to lock the route lever in the position corresponding to " line clear ", the mechanical or electric interdependence of the route locking and the signal compel the signalman to carry out this operation (69), before it is possible to set the corresponding signal to " line clear ". In the case of locking the route lever in the final position (position interlocked with the signal) this compulsion generally depends on the interdependence with the official managing the traffic.

Compulsion to lock.

Question 69.

In the group blocking adopted in Saxony the route levers are not interlocked in the normal position; consequently, there is no compulsion for any operation of this kind. But, on the other hand, the signal levers are locked in the " danger " position by the previous blocking operation, and before release the connexions for the route and consequently also the necessary switch movements cannot be made. Consequently the signalman has to close his sections by blocking his signal if he wants to move his switches for shunting operations or in order to make a new route. Thus this blocking replaces the otherwise very usual locking of the route levers in their normal positions, and at the same time when the section is closed, it forms a

necessary condition for the dispatch of unlocking, without which no other train can approach.

In Prussia, in the case of installations where there is section blocking after a train has entered, the signal lever has in the first place to be locked in the " danger " position. This is effected by a double key simultaneously with the blocking of the end field, by which the section behind is open. This blocking of the end field is however only temporary and again cancelled when the route lever brought back into the normal position and then locking the signal, is locked by the blocking. The latter operation, which at the same time releases the unlocking field of the official in charge of the traffic, is thus absolutery compulsory, as until it has been carried out the official cannot give permission for another train to enter, nor can the signal be set to " line clear ". Such a compulsion does not exist in Prussia in the case of departure tracks.

In the cases of departures the compulsion for the locking of the route levers in their normal position, and for the simultaneous closing and protection of the section against other departures is more and more effected by the electric interlocking of the signals (for making the signals fly to " danger ") which when the train passes over rail contacts makes the signal fly automatically to " danger " and naturally only makes it possible to set it to " line clear " after the signal lever has been moved back into the " danger " position.

But when the signal lever has been moved into this " danger " position, it is locked in a simple way by a signal lever bolt connected with a locking bar, and this is only released when the signal lever or route lever locking has been completed; so that another train can only be admitted when the different interdependent block operations have been carried out in the proper order.

In principle, there is naturally no objection to the application of such signal coupling devices to entrance or block signals. Up to the present, however, this application has as a rule been limited to cases in which sufficient safety was not obtainable by any other method.

Locking by continuous or alternating current.

Question 70.

As regard the locking gear (70) for hand-operated installations, alternating current is as a rule preferred. Continuous-current interlocking is used, exclusively in Wurtemberg, chiefly in Denmark, and in some cases by other administrations when the locked route is to be cleared by the trains.

In the case of power installations, continuous current is chiefly used.

Route locking during the journey.

Questions 71, 72.

The possibility afforded by the electric route interlocking to prevent with certainty any movement of the switches while the train is passing, and that independently of the switchman, is recognized by nearly all the administrations as of much importance from the point of view of safety, and utilized; the locking (71) being effected in the " line clear " position, and the release either by the train itself or from a spot at which it is possible to ascertain that the passage of the train has been completed.

The method and means of release (72) depend on the nature of the locking

appliances used (continuous-current or alternating-current installations); it is effected either by means of a special alternating-current unlocking field at the station itself, in which case the official in charge has to attend to the apparatus, or is made dependent on his co-operation, or is effected by the train itself, which unlocks the locking when passing over a rail contact.

Group interlocking. Route contacts.

Questions 73, 74.

The answers of the different managements on the subject of interlocking several route levers by one common applianee (73) show that such appliances are largely adopted, but that there are also very great differences in the construction and action of such appliances.

The most usual arrangement is that every route is it is true locked in the normal position (" route closed ") by a separate locking gear, but that for locking in the " line clear " position there is only one common locking gear for each group of routes which mutually exclude each other. Consequently for unlocking this only one unlocking field is necessary, which has to be operated after the train has passed, while for releasing the route levers when in their normal position there are as a rule as many unlocking fields, as there are routes to be considered.

In Bavaria, the arrangement is simplified in so far that the incompatible routes can be released by the official controlling the traffic by a blocking field or the main block, after the circuit has been made by special contacts, and the route locking effected for the passing of a train can be cleared by means of a second blocking field. The number of positions of the contacts corresponds to the number of route making fields in the installation. Similar arrangements are also to be found in Baden.

In the case of the group blocking introduced since 1886 in Saxony and mentioned under (69), there is one common locking gear (generally consisting of two parts) at the apparatus, both for releasing as well as locking during the passage of a train, for incompatible routes; the one part locking in its normal position the signal, the other part intended to keep the routes locked while the train passes.

The current required for releasing a signal only passes to the signal-blocking field, if on the one hand the official managing the traffic connects the conductor for the route in question by means of a special key (consenting contact) with the source of current (station blocking with magneto), and on the other the correct route lever is thrown over in the signal cabin and locked, the corresponding conductor being then automatically connected with the signal blocking field.

The unlocking of the route locking after the train has passed cannot be effected until the signals have been locked electrically at " danger " and requires either the co-operation of the official managing the traffic, at the corresponding contact, or that of the train by means of a rail contact.

The Rank system, which is much used in Austria, is nearly related to the Saxon group locking with consenting contacts. In this system, sliding contacts are used instead of the consenting contacts operated with a key; these contacts are moved on a slide plate arranged like a plan of the tracks, so that the position of the contact at the same time shows clearly that the track in question is occupied.

In the case of single-track railways the use, of such group blocking makes it possible to treat the entrances and departures on one side of the station as a group, as they are incompatible; and very simple block arrangements result.

The use of group blocking involves the connexion of the route lever bars with contacts (74), which, as already stated, only make the circuit for the releasing current when the bars have made the proper routes. But sometimes contacts are also placed on the route bars in order to make circuits for the electric interlocking of signal arms and releasing block keys and route locks.

At present but little need has been felt that the electric interlocking of signals or switches should be effected without the action of the route lever (75). Such appliances are used in a few cases, for instance in very simple installations. Prussia however intends to apply such a system in the case of power installations.

Interlocking without action of route lever.

Question 75.

In the cases in which sufficient experience is available, the electrical route-interlocking has without exception given favourable results (76). There is no expression of opinion in its disfavour even in cases of much traffic. Several administrations also speak in favour of mechanical route-interlocking. It is however to be noted that Prussia does not intend to use mechanical interlocking in future. Electrical route-interlocking is also strongly recommended in the case of new installations (77); in some cases, attention is also drawn to the fact that under circumstances mechanical interlocking may also be advisable.

Reliability.

Questions 76, 77.

78-94 : Measures to prevent the premature operation of switches.

As a rule pressure or contact treadles are used in order to prevent the operation of the switches taken from the facing side, before the whole of the train has passed (78). The Austrian North Western and the South Northern have however been giving up the use of pressure and contact treadles for this purpose, and prefer switch control locks together with mechanical and electrical route-interlocking. Bavaria has since 1896 been replacing them by electrical appliances.

Keeping switch fixed while the train passes.

Question 78.

In Alsace-Lorraine pressure and contact treadles are used at switches also when taken from the trailing side.

Time locks, which lock the switch for a certain time (79), are as a rule not much used for the purpose mentioned under 78. Experiments made in Saxony and Baden with these appliances have not given favourable results. Owing the technical and practical difficulties they are no longer used in these countries.

Time locks.

Question 79.

Only in a few instances, but in a number of different shapes, are mechanical devices, such as pressure or contact treadles, used in combination with the electrical appliances (80). Alsace-Lorraine for instance has pressure treadle levers in the continuous-current block apparatus; Saxony has canting rails with electric contacts and Wurtemberg lever locks in combination with insulated rails. In Austria-Hungary and in Switzerland, pressure or contact rails are used together with insulated rails and lever locks, in order to make the operation of a switch impos-

Pressure and contact treadles.

Questions 80, 81, 82, 83.

sible before the whole train has passed. The Austrian Southern also uses the so-called contact treadles. Two of these, each 7 metres (23 feet) long, are placed behind each other, or next the two rails so as to overlap a little. The electric release of a continuous-current lock, making it possible to operate the signal and unlock the route locking, is only made possible after both treadles have been pressed down simultaneously and have once more resumed their former level.

The proper length of the treadles (81) is generally given as 10 to 12 metres (32 ft. 10 in. to 39 ft. 4 in.). In Saxony there are some 13·5 metres (44 ft. 3 $^1/_2$ in.) long, and in Wurtemberg 15 metres (49 ft. 3 in.). The important factor in the settlement of this question is naturally the greatest distance between wheels in regular use.

All the lengths mentioned above have proved satisfactory from the point of view of construction (82). Some administrations however state that they are not yet able to give a definite opinion on the point.

Pressure and contact treadles have as yet only been used on curves (83) by a few German and Austrian administrations, and also in Rumania, and that with good results. According to Prussian experience, the smallest radius admissible is 180 metres (9 chains). It is observed that these require more careful maintenance, as they are very liable to jam if there is any creeping. Rumania remarks that good results with contact treadles are only obtained at curves if they placed next the superelevated rail.

In addition to the mechanical appliances mentioned for locking the switch in position till the whole of the train has passed, all the administrations we are considering also extensively use perely-electrical devices (84).

Locking by electrical devices. Insulated rails. Rail contacts.

The most usual of these is the electrical block apparatus for locking the route levers in the normal or in the " line clear " position.

Questions 84, 85, 86, 87, 88, 89, 90.

Insulated rails placed before the switch are used for the purpose; while the train is passing over them the switch lever is locked.

Bavaria attains this object in the case of hand-operated installations by fitting a special bolt to each of the corresponding switch levers; this bolt can be operated electrically from the signal box by turning an indicator handle if the insulated rail before the switch is unoccupied. If it is occupied and the signalman should turn the handle, the current would be short-circuited and pass to earth through the axle on the insulated rail and would not reach the bolt. The signalman is informed that a train is passing over the insulated rail or is standing on it by the sounding of an electric bell in the signal cabin. In addition there is an indicator in the form of a small red or white disk showing whether the switch lever is free or is locked.

This arrangement is more recently also used for clearing the routes; with this object in view it is also equipped with a mechanically-acting wheel detector.

In order to arrange matters so that the action (85) of the purely-electrical devices does not terminate before the last axle has passed, insulated rails (86) have been used with good results; instead of them contact treadles can also be used. In other cases the necessary safety against premature operation is obtained by placing the

rail contacts at more than a train length from the spot which the whole train has to pass, before it is possible to operate the electric contact gear.

That insulated rails (87) can be used not only for preventing the premature operation of switches and other block apparatus, but can also have important applications for releasing electric arm interlocking, is evident from what has been stated under (62), as insulated rails belong to the class of rail contacts and can be used like them, so as to protect a departing train by making it automatically close the section.

Wurtemberg also uses insulated rails for controlling the departure of trains, the Austrian Southern Railway also for closing an entrance section until the train which has previously entered has departed, also for announcing arrivals and for operating bells when a train approaches.

Switzerland has as yet not used any insulated rails.

The fishing of insulated rails (88) is nearly always effected by wooden fishplates (made of hornbeam or of Australian hardwood), which have given good results. In Saxony, the action of the wooden fishplates is reinforced by the addition of a short longitudinal sleeper made of oak and supported on iron transverse sleepers; this not only adds to the stiffness of the rail at the insulated joint, but also materially helps to prevent any movement of the rail ends relatively to each other.

On the Austrian Southern Railway, good results have also been attained by wooden framing placed under the joint.

When rail contacts are used, the circuits are as a rule made (89) as follows: when the train passes on to the rail this is bent and closes a mercury circuit. Experiments have been made recently with the so-called drop contacts of Messrs. Siemens & Halske, in combination with electric block key bolts for intermittent continuous current, and good results have been obtained. As compared with the usual arrangement, this appliance has the advantage that after the rail has once been bent, a number of current impulses are required for interlocking; these are obtained in a very simple manner by the mercury drop contact by the intermittent outflow of the mercury forming the contact. The use of these appliances will be particularly advantageous in the cases where there would otherwise be a possibility of interlocking produced by the action of atmospheric electricity or of stray currents. The co-operation of the train in the safety measures, which results from the use of simple rail contacts, is no doubt a very valuable but not quite perfect method; but there is no doubt that it is much improved from the point of view of safety by the automatic production of intermittent current.

As the above shows, insulated rails and rail contacts (90) are principally used for locking and unlocking levers and other block apparatus in the cabin; sometimes they are also used, as in Wurtemberg, Denmark and Russia, for warning the signalman. Other similar applications are also made in individual cases.

It seems more especially very natural that such appliances should be used in order to announce automatically the approach of a train at a level crossing where

there is a fair amount of traffic, so that the gates may only be closed a short time before the train arrives. It is also desirable that a train should automatically give notice of its approach, so that any necessary precautions may be taken, at level crossings without gate keepers on secondary lines; also at places where the line leaves a tunnel, or goes over and iron bridge, and a busy street is alongside, where horses may easily be terrified by the sudden appearance or the noise of the train. But all these methods of announcement have unfortunately the disadvantage, that their failure does not notify itself and may consequently give rise to misunderstandings resulting in serious accidents. The advantage obtained in the one way is counterbalanced by the serious extra responsibility resting on the maintenance staff. It is accordingly intelligible that there is a certain hesitation in adopting such methods.

Other locking devices.
Question 91.

As regards the prevention of the premature operation of switches, besides rail contacts, insulated rails and treadles, there are also some simple mechanical devices in use (compare 78 . Thus the Austrian North Western and the South Northern use switch control levers for this purpose, depending on the mechanical and electrical route interlocking gear (91); such control locks with portable keys have also given very good results in many other cases for obtaining relations in simple switch and signal installations and for combinations of switches and switch blocks.

The electrical devices used in Bavaria instead of pressure and contact treadles, especially the much-used lever locks, have already been referred to under 78 and 84.

Field of application.
Question 92.

It is a nearly-generally accepted opinion, that it is desirable that all switches taken from the facing side should be fitted with devices to prevent the premature operation of the switch (92). There are only a few administrations who consider that it is sufficient if such devices are limited to those cases, in which the switch cannot be properly seen from the cabin and has to be operated immediately after the train has passed.

There is but little need to extend the use of these devices to switches which are taken from the trailing side. This as a rule only has to be considered in the case of switches which are at a great distance or cannot be seen from the cabin and are much used for shunting operations.

Reliability.
Questions 93, 94.

No particular difficulties in the service or in maintenance (93) have arisen from the use of these safety appliances for preventing the premature operation of switches. The general opinion on the contrary is that they have a favourable influence on the carrying out of the service.

An unfavourable opinion is however expressed in several cases as regards time locks (compare 79). The St. Gothard Railway does not consider them suitable for stations at which much shunting work takes place. In Rumania also they did not in all cases give favourable results. It has already been mentioned that in Saxony and Baden technical and maintenance difficulties arose in connexion with the time locks, and therefore their use was given up.

Nevertheless they are a simple and valuable auxiliary for the locking of solitary switches; several administrations will in the future 94 use them as well as pressure and contact treadles and insulated rails. When several switches however have to be locked for one given train, the preference is as a rule given to electric route-interlocking.

Alsace-Lorraine prefers the insulated rail with added rail contact connected with a continuous-current blocking field on the locking of a block key. The Austrian Southern considers that the best to use at large stations with block system are electro-mechanical treadle rails; at smaller stations, pressure treadles; and at switches not otherwise protected, Schilhan treadle rails.

Denmark, Sweden and Switzerland do not speak in favour of any definite system, partly because enough experience is not yet available.

95-103 : Graphic representation of the occupation of platform tracke.

Graphic representations with fixed indicators.

Questions 95, 96.

In order to facilitate the management of traffic at very busy stations, some of the Prussian administrations use graphic representations (95), in which the occupation of the tracks is marked in advance (96) in accordance with the time-tables.

The traffic and maintenance offices in Saxony use such representations in the form of plans showing the operation of the traffic only in order to be able to judge the effect of proposed alterations in the operation of the traffic or in the arrangement of the tracks. Such representations are not used in Bavaria, Baden and on the Swiss Federal Railway, but on the other hand there are appliances provided (block relations, order of route levers) at the chief apparatus or at the cabin which, when a train is there, close the entrance to the track in question until that train has taken its departure and the occupied or unoccupied condition of the track is notified in the cabin by coloured disks.

Movable indicators.

Questions 97, 98, 99, 100.

Wurtemberg, in order to show the occupation of the tracks, only uses indicating plates.

In cases of the latter kind the occupation marks are movable, while in the former they are not (97). A simple method of graphically representing the occupation of the tracks by means of movable marks is as a rule available in the case where the separate lines or routes are made by the official managing the traffic by operating blocking fields or contact devices, in which the locked or unlocked condition of each separate route is indicated by coloured disks appearing behind small windows in the signalling apparatus.

These signal windows are as a rule arranged in the same order as the corresponding rails, so that the state of occupation is easily grasped. This system of graphical representation is particularly developed in the Rank block apparatus which has already been mentioned (compare 73) in which the releasing contacts are closed by buttons, which can be moved along the lines on a diagrammatic plan of the station, which represent the tracks.

In the case of the appliances commonly used in Bavaria and Baden and on the Swiss Federal Railway the change of the coloured disks, showing the occupation of the tracks, is effected when the route lever at the station or signal cabin is operated.

Any system of effecting the movement of the marks indicating the occupation of the tracks from the outside (98), such as automatic adjustment produced by the movement of the train on the tracks in question, does not seem to be in use anywhere; but on the other hand the setting of the marks often has a restraining or permissive effect on the signal apparatus (99).

We may also include here the automatic electric device of Messrs. Siemens & Halske (compare 64), in which the succession of the shunting operations is marked on a strip of paper by means of punched holes, and is then automatically carried out by the apparatus.

Other relations between the graphic representations and the train movements and the occupation of the track concerned (100) have as yet not been effected.

Field of application of graphic representations.

Questions 101, 102, 103.

The graphic representations of the occupation of the track, mentioned above, are by no means limited to platform tracks; they are also frequently extended (102), in so far as they are used at all, to other entrance and departure tracks. This applies especially if we also include among them the marks appearing in the case of electric unlocking appliances. With this extended meaning attached, it also applies in some cases to locomotives running light, while graphic representations proper, of the occupation of the track (101), are not used in these cases and in the case of shunting operations.

The arrangements mentioned are stated to give good results both as regards the facilitation of the service and as regards safety (103). The use of graphic representations has proved especially valuable when special trains have to be intercalated.

In organizing the train service at a large station, as far as the point of view of safety is concerned, the importance of such graphic representations is small as compared with the further development of electrical checking devices and means of communication, which make it possible for the different apparatus to work separately and yet form one united whole from the point of view of safety.

CONCLUSIONS.

The chief conclusions to be drawn from the answers and information concerning question X received, are as follows :

Hand-operation.

1° The newer developments in the methods of operating switches from a distance have extended more especially in the direction of double-wire transmissions, and

have resulted in appliances giving results which are satisfactory from the point of view of safety, although still capable of improvement; there is therefore no reason from departing from this direction;

2° The operation of switches by means of rod transmissions is preferred to a smaller extent, in some cases only under special local conditions; such transmissions are less liable to fracture, but any fracture is not controlled automatically as easily as in the case of double-wire transmissions;

3° The operation of switches at a distance should also be combined with locking (switch bolts, blade locking, or should be made safe by separate subsequent locking (control locking);

4° In the case of important switches taken from the facing side, whether the transmission be by rod or by double wire, it is in many cases considered necessary to have control locking in addition to the locking of the cabin apparatus;

5° The use of reacting cuttable switch locks with separate operation of the switch blades has given good results. The most usual way of securing the blade is by a thrust obtained from a special point of support, but switch locks in which the blade and stock rail are clamped together are now used more extensively;

6° Switching gear with wire transmissions have for many years given good results, both those which include gravity stretchers and those which do not; but the addition of gravity stretchers makes further control and automatic blocking possible. The required degree of reliability of the switching gear is obtained by protective casings, by a suitable size of the weights and a suitable height of drop;

7° The locking of switches is only applied to a limited extent, apart from the control locking of switches which are far off;

8° Double-wire transmissions are exclusively used for the operation of signals at a distance;

9° The intercalation of control locks in the wire transmissions of signals is not quite without influence on the certainty of the operation; nevertheless it is frequently used in order to simplify the installations;

10° For the same reason, the operation of the distant and of the main signal is also frequently effected by one double-wire transmission only. Operation by two double-wire transmissions with separate interlocked levers, is more certain and hence preferred by sundry administrations;

11° It is absolutely necessary that the fracture of the signal wire transmission should result in the signal being at " danger ". Where gravity stretchers are used at all, they are generally also used to assist in producing this result;

12° The use of ball bearings and roller bearings in switch and particularly in

signal installations has proved advantageous; but as yet they are used only to a limited extent;

13° Electric signal arm interlocking has proved a valuable auxiliary in the case of mechanical installations;

14° Improvements in hand-operated installations are attainable and are to be expected, in reducing frictional resistances, in giving better protection against disturbing outside influences, in improving automatic controlling, locking and blocking appliances, as well as in the further addition of electric auxiliary appliances.

Power-operation.

15° Only electricity and compressed air with electrical control have given promising results as sources of power for the operation of large installations;

16° In individual cases good results have also been obtained by compressed carbonic acid, with electrical control;

17° Up to the present the number of failures is greater in the case of power-operated installations than in that of hand-operated installations. The former still want special expert maintenance and the capital outlay is greater than with the latter.

But with power installations a large amount of traffic can be dealt with more quickly than with hand installations; a number of safety conditions when operations are carried out at a distance can be satisfied better with the former than with the latter; in many cases the former also results in a saving of staff;

18° Their further extension at suitable places, especially in the case of new installations at stations with much traffic, is contemplated by those administrations who have tried them on a larger scale. The further development of such systems of power operation can therefore be looked upon as certain;

19° As regards the railways we are here considering, more experience is available about electric installations than about pneumatic. The question which of the two sources of power, electricity or compressed air, is to be definitely preferred, is as yet undecided;

20° Combination of hand-operated and power-operated appliances in one apparatus has been tried with fair success;

21° The simultaneous operation of the switches of a whole route, possible in power installations, is not effected and one limits oneself to operating each switch separately or operating two related switches simultaneously;

22° The electrical installations are operated with continuous current exclusively;

but the question of operating with single-phase or three-phase current is under consideration.

Signals and Switches generally.

23° The control of the completion of the operation of a signal at a distance is generally limited to the control of the "danger" and "line clear" positions. But there are also in use controlling devices with special checking for any doubtful intermediate positions;

24° The electric control of the position of the signal is as a rule not extended to distant signals, although these, from the point of view of their importance, have as a rule not less need for control than the main signals;

25° Spring switches can be set at a distance, in cases of hand-operation as well as power-operation, with as much certainty as ordinary switches;

26° The setting of barriers at a distance is often included in the route interlocking, that of level-crossing gates seldom;

27° The action of the train on the apparatus, by means of rail contacts and insulated rails, has given good results; this system has been applied extensively;

28° On the other hand, devices to enable the cabin to act on the train, so that a rail contact or treadle will produce a signal in the cab or will apply the continuous brake, are still in the experimental stage;

29° Opinions are divided on the question, whether it is desirable to apply the brakes in this way from outside;

30° Several administrations use sand tracks, the switches of which are operated from the cabin;

31° Electric track indicators have been successfully used for indicating the tracks at gravity sidings;

32° It has been proposed to set the switches automatically at gravity sidings with electrical operation.

Electric interlocking of route levers.

33° The electric interlocking of route levers (locking with electrical release) is very much preferred to purely-mechanical locking and unlocking;

34° The route interlocking is as a rule made dependent on other operations on the cabin in such a way that its operation is compulsory.

The co-operation of the train by means of rail contacts is utilized in this connection with advantage;

35° Electric interlocking gear works in most cases very satisfactorily with alternating current;

36° The locking of several routes by one single appliance (group locking) has been introduced in several stages of development and has given good results.

Prevention of the premature operation of switches.

37° The locking in position of a switch while a train passes, so as to prevent its premature operation by the signalman, is generally recognized to be desirable. This safety measure is most important in the case of switches taken from the facing side;

38° Pressure or contact treadles, partly combined with electrical appliances, are extensively used for this purpose, and with good results; time locks are used less, and some administrations object to these as unfavourable results were obtained with them;

39° Safety measures consisting of electrical appliances only (unlocking gear, rail contacts, insulated rails combined with electric lever locks) are used extensively for this purpose, and with success;

40° Reliable devices have been worked out for the fishjoints at the ends of insulated rails; in some cases they are combined with extra supports;

41° Where there is little traffic and only a small number of switches, good results are obtained by using control locks at the switches for locking them in position, with portable keys.

Graphic representation of the occupation of tracks.

42° Graphic representations of the occupation of tracks are as a rule not limited to platform tracks, but are generally also extended, the the form of plans of the traffic operation, to other entrance or departure tracks, the occupation of which is determined in advance in accordance with the time-table. They have proved particularly useful for the intercalation of special trains;

43° At some stations the occupation of the different tracks is shown in the office of the official managing the traffic by removable indicator plates. The marks appearing at the signal windows of the block apparatus also form, in a sense, a graphic representation of the occupation of the tracks.

REPORT N° 3

(America)

By E. C. CARTER,

CHIEF ENGINEER, CHICAGO AND NORTH WESTERN RAILWAY.

A review of the conditions existing in the United States at the present time, with reference to the operation of switches and signals (II of section 3), develops the following :

A. — Centralized installations for operating switches and signals are limited :

First, to those in which the required movements of the functions are made by manual force through mechanical connections brought to a central point, and

Second, to those in which some form of stored power is controlled from a central point for such operations.

The first is represented by the mechanical interlocking mechanism which is in such general use throughout the world as to require no particular description. There has been, in America, very little, if any, change in the details of the apparatus or of its installation for a number of years. The use of 1 inch pipe connections is universal for the operation of switches, movable point frogs, draw bridge couplers, and their respective locks, compensated for the effects of temperature changes by an equalizing system of cranks and levers. It is also very generally used for the operation of home signals. Wire connections (one wire for the front connection and one for the back) are still used for the operation of distant signals which can be

*

located not over 1,300 to 2,000 feet from the tower, but when the signal has to be located at a greater distance, liquid carbonic acid gas, stored in steel bottles, or electricity, derived from a battery, is used as the source of operating power, located at the signal and controlled electrically from the tower.

The second comprises those in which hydraulic, pneumatic, or electric power is stored and used for the operation of the various functions.

Owing to the severe climatic conditions which continue in winter for from two to four months throughout the northern portion of America the use of hydraulic switch and signal apparatus is subject to such derangement and such interruptions in operation as to be very unsatisfactory. A small number of plants of this type have been installed but have been discontinued and replaced by other kinds which are free from the troubles which are inseparable from the use of liquids as a means of power transmission under such climatic conditions.

The use of compressed air has been quite extensive and has given a very fair degree of satisfaction as the means for operating switch and signal installations in this country. This kind of power application is represented by two types :

a) The low pressure, in which the air is used at a pressure of from 15 to 25 lb. per square inch, and,

b) The high pressure, in which the air is used at from 80 to 100 lb. per square inch.

The low pressure type has many points of excellence, but for some reason has not become very popular, probably on account of the great number of pipes leading to the switches and signals. Inquiry developes the fact that no plants of this type have been installed since 1905 and also that, as the existing plants require extensive reconstruction or renewal, this type is giving place to some form of all-electric apparatus.

The high pressure type is represented only by the Westinghouse Electro-pneumatic system. A very large number of plants at large and complicated junction points and terminals have been installed and are in very satisfactory operation throughout the entire country. It is a recognized fact, however, that compressed air under high pressure is subject to a number of characteristic losses in efficiency, which will limit its use. The loss on account of the heat generated, due to the work of compression, is unavoidable and amounts to from 50 to 60 per cent of the energy expended in storing this kind of power. The losses due to leaks in the distributing pipes are variable but as the system grows older increase, and often become an element of serious expense, necessitating extensive repairs and renewals.

The application of all-electric interlocking plants has made rapid strides in the last eight or ten years and, as this type offers very superior advantages, it bids fair to take the lead. The reasons for this are :

1° Its greater flexibility in application and use;

2° In the storage of the power and its distribution the lossees can be reduced to a very small figure;

3° The distribution and application of the power is free from any inherent troubles due to variations or extremes of temperature.

This type of interlocking development is represented by the product of four principal companies.

The common feature in all of the designs is the use of motors for the movement of switches by means of gears, a screw, a worm or by a cam motion plate, any one of these mechanical devices being susceptible of development to meet the requirements. Signals are operated generally by motor driven gears, dwarf signals sometimes being operated by solenoids.

All power interlocking is arranged so that the completion of the movement of the switch or signal gives a return indication at the machine in the tower, releasing the mechanical locking and insuring that the position of the switch or signal, as the case may be, correspsnds with that of the operating lever.

The locking between the levers of the machine is mechanical, being generally of the same type as that for mechanical interlocking plants, though not made nearly so heavy, not being called on to withstand such applications of force as is usual in the manipulation of mechanical levers.

Electric locking of the levers in the interlocking machine may be arranged to effect the following in either mechanical or power operated plants :

Advance locking. — This is generally used at points where trains pass at high speeds, to prevent the taking away of the route which has been cleared for an approaching train, the switch levers remaining locked until the train has passed or until the signalman has operated a releasing device which is arranged to take time, thus repuiring deliberation and giving an interval during which the train can be stopped. The signal levers are never included in this advance locking but can, in their proper rotation, be restored to their normal positions at any time.

Detector bar locking. — Electric locking is used for this purpose in connection with track circuits in yards where such circuits are used in place of mechanical detector bars.

Route locking. — This form of electric locking is used to lock all switches in a route so that they cannot be moved in advance of a train after the train has accepted the route, even though the mechanical locking on the machine has been released by the leverman in placing his signal lever in the normal position.

Release route locking. — This form of electric locking effects the consecutive release of each switch as and after the rear of the train has passed it and is only used in large and complicated terminals to save time.

Check locking is that form of electric locking between adjacent interlocking towers which are so near each other as to call for co-operative action of the signalmen in them.

Route levers, as known in Europe, have never become popular in the United States, it being considered an essential operating requirement that the plant should permit of any possible route combination of switches being given so as to cover irregular movements and emergencies.

B. — The use of track circuits in place of detector bars has become usual in complicated terminals and is considered as being safer than any mechanical devices for this purpose, it being possible with such circuits to prevent the movement of the switches while the train is passing over them and may be arranged so that the train is wholly clear of any adjoining track or switch before another train can be permitted to pass that point. In plants where the spacing of the switches is such as to permit it, mechanical detector bars, either inside or outside of the rail, are still generally used, though it is evident that, with the increasing use of heavier rail sections which have materially wider heads, such use must be limited to bars of the inside type.

In heavily worked, large, and complicated terminals a miniature track model is generally provided on the interlocking machine for the information and convenience of the levermen. Formerly, this model was arranged to show the movement of the switches corresponding to the movement of the levers, but with the greater perfection of the return indication apparatus which controls the operation of completing the stroke of the lever, the model has been used to indicate the occupation of tracks or of two or more sections of a track as may be needed. An indication is often provided showing the failure of any train to wholly clear an adjoining track. One of the most complete and elaborate installations of this later type is that provided for the operation of the new Union Terminal at Washington, D. C. Each standing track in the depot has an independent track circuit fed through a resistance from a single supply circuit, the track relays all being in the tower at the outer end of the yard. In the tower and over the interlocking machine is arranged a large track model, covered with ground glass, on which the track arrangement of the station is outlined. So long as a track is unoccupied and is not fouled by cars on an adjoining track, that particular track on the model is illuminated from behind the glass. As soon as it is occupied by a car or train the lights are extinguished. It will be seen from this that these indications are given from a closed circuit, which is used preferably on account of its indicating at once any derangement in the circuits and is generally considered to be the only safe way in which track circuits for this or any other purpose can be used.

This station is also provided with a very complete system of communication between the director of the interlocking tower, the train conductors on the different departure platforms and the gateman controlling the admission of passengers to

those platforms. In the interlocking tower, in front of the director, there is a bank of indicator lights arranged one above the other, three for each track, the upper light being the return indication from the train conductor, the middle light an indication to the conductor and the gateman, and the lower light an indication from the gateman. Adjoining each gate there are two incandescent glow lights on the circuit, one above the other, connected in such a way that the gateman, by inserting a special key, can complete a circuit to the tower.

At four points, distributed along the platform, are located boxes on the columns supporting the umbrella shed, each box having two glow lights, one above the other, the boxes being so arranged that the conductor of a train, by inserting a special key, can likewise complete a circuit with the tower. The method of using this system of communication is as follows;

One minute before the departure time of the train, the conductor inserts his key in one of the boxes on the platform and turning it closes the circuit which lights the upper light for the corresponding track in the bank of lights in front of the tower director and likewise lighting the upper of the two glow lights at the gate. If the director is ready to have the routes given for this train, he presses a button which puts out the top light given by the conductor and lights the one next below it and lights the top light in each of the boxes along the platform and puts out the upper and lights the lower of the two lights at the gate. When the time has arrived for the train to go, the gateman closes his gate and with his key puts out the light at the gate. This also puts out the upper and lights the lower of the tower indicator lights, in this way advising the conductor and the towerman simultaneously that the train may leave. The conductor may then give his usual starting signal to the engine runner to go, which he then does, provided the proper fixed signal is clear. This arrangement provides a very simple and accurate system for transmitting the required information and works perfectly.

C. — The use of diagrams for facilitating the full utilization of tracks along passenger platforms.

Inquiry of the roads in this country having the largest terminals developes the fact that no such diagrams are used or are considered as being necessary for the distribution of trains at platforms, experience having proved that the familiarity of the director in the tower with the station lay-out and the information which he receives in advance as to the trains to be handled is such that the desired results can be better obtained by relying upon his skill.

The foregoing covers about all of the points that are raised by the questions which are submitted for discussion, but it is believed that in this same connection it will be interesting to present a discussion which has been under consideration by those interested in signalling of the various railways of the United States during the last three years. In general, the practice in America has been to give the indications of fixed semaphore signals for both interlocking and automatic block signals, in the

lower right hand quadrant, usually by two positions, the home signal being horizontal for " stop " and diagonally downward or vertically downward for " proceed ", and the distant or caution signal (the end of the blade being of a different form from that of the home signal, being notched or fish tailed, whereas the end of the home signal is square) indicating in the horizontal position "caution" and diagonally downward or vertically downward indicating " clear ". The extensive application of automatic semaphore block signals and the attempt to carry the block working through more or less complicated interlockings has led to considerable diversity of practice on different lines, and the automatic block semaphore, both home and distant, being of the same form as the home and distant semaphores for interlocking plants has led most naturally to a possible confusion on the part of the engine runner in the interpretation to be given for a given signal indication, especially when in its normal position, which, for an interlocked semaphore indicates " stop and stay " and for an automatic block signal semaphore indicates " stop and proceed with train under control ". The practice on different roads in connection with interlocked semaphores at points where a number of routes are to be indicated has also varied, a number of the older lines having a home signal blade for each route, placed one above the other on a single mast, and other roads for similar situations having only two, the upper for the main high speed route and the lower for diverging routes.

Figure or letter indicators combined with the lower blades, under the two blade system have been tried but were discarded as of no value corresponding to the complication or cost due to their use.

The consolidation of different railway properties under one management has brought together lines having both systems in use and the necessity for unifying the practice over the whole of such a consolidated line and doing it in such a way as would provide for the future as well as the present requirements led to a very prolonged and exhaustive investigation by Committees appointed by the larger lines interested in the question, and later by Committees of Railway Signal and Maintenance of Way Associations. The result of these investigations was the statement of a series of fundamental principals and of the rules which should govern any applications under those principals.

The first and most radical departure was the use of the upper right hand quadrant for giving signal indications, in this respect following the German practice.

Secondly, the giving of three indications by one signal blade, one by the blade displayed in a horizontal position and pointing to the right, one by the blade pointing upwardly at an angle of 45° and one by the blade pointing in a vertical direction upwardly.

Thirdly, the use of a second blade below the first, which in turn gives three indications by similar positions to those of the first or upper blade.

Fourthly, the distinguishing of interlocked semaphore signals from automatic semaphore signals by having the ends of the interlocked signal blades (when the blades were in a horizontal position) in the same vertical line, and by having the

ends of the automatic semaphore signals (when the blades were in a horizontal position) so arranged that the upper blade projected further to the right than the lower blade.

The night signal lights were correspondingly arranged, one being vertically above the other for interlocked signals and for automatic signals the lower light being located diagonally below and to the left of the upper light.

The above combinations of three positions for two signals permitted of giving a considerable number of indications which were thought necessary for giving information to direct the movement at the high speeds at present required for through limited and special service trains.

It is generally admitted that the night indications should be given by lights of distinctive color, and the difficulty in giving so many combinations as above required has been solved by the use of green, yellow and red lights for the three positions of vertical, 45 degrees, and horizontal, though it appears to the writer that by far the most logical solution would have been green, red and green, and red for the corresponding positions, the red and green from one source of light having been proven by years of use on one or two of the largest systems in the country to be absolutely distinct and reliable.

Up to the point where two blades have been decided on for giving indications in combination, there has been a fair degree of unanimity in the ideas of those responsible for the system, but some divergence of opinion has developed as to the system by which the combinations shall be made and the great danger appears to be that greater confusion may result as between the practice of different roads in this respect than has existed under the systems which have been in use heretofore.

It is the writer's personal opinion, that simplicity should never be sacrificed in so grave a matter as giving indications for governing the runner of high speed trains, in order to give modifying instructions for slower speed movements. The time for correct action by the runner of a high speed train is so short that the message to be conveyed by signals must be so simple that its interpretation is intuitive and not the result of reasoning. The message, therefore, must be limited to that which can be instantly comprehended by any one who can be expected to reach the position of runner and not by the highest, or even the average mental development to be found in runners as a class. It is the firm conviction of the writer that, taking into consideration all of the conditions surrounding the men whose duty it is to run an engine, the care of the machinery, the looking out for train order, block, and interlocking signals, the graduation of power for grades and curves, taking water at speed, station stops, and a great many other exacting requirements, that the placing upon them of the responsibility of correctly interpreting a combination of signal indications which takes a variety of mental operations, is a long step away from safe practice. It would seem much safer to give the indications by one blade, which, if need be, can have four positions with corresponding night indications, four appearing to cover all present requirements, the blade pointing to the right of

the signal mast as seen by an approaching train whose movement is to be governed by it.

1° The blade in a horizontal position, red light at night;
2° The blade vertically upward, green light at night;
3° The blade inclined upward at an angle of 45°, a red and green light at night;
4° The blade inclined downward at an angle of 45° a yellow light at night.

The corresponding indications would then be as follows :

1° Stop signal;
2° Clear signal. Proceed. Next signal is also in position to be passed, being either clear or at caution;
3° Caution signal. Proceed at such speed as will admit of stopping at next signal, which may be at stop or at caution;
4° Caution signal. Proceed at such limited speed as is safe to take a diverging route from the main line from this junction or cross-over.

As discriminating between semaphores for interlocking and those for automatic block signals, there can be placed upon the mast a bracket projecting to the left, whose outer end shall have the same relation to the mast that the outer end of the semaphore casting has to the left of the mast for interlocked signals, and on the outer end of which a white light can be placed at night as a marker. For automatic block semaphores this bracket can be projected further to the left so that its outer end will appear to be materially further from the mast than is the semaphore casting upon that side and on the outer end of which a white light can be placed at night as a marker.

It is believed that such an arrangement of signals as this can be made to cover all of the necessary moves in territory where high speed is permitted and that in terminals or other points where the speed is necessarily limited, as compared with that on the open road, a dwarf signal indication can be given on the ground at the foot of or below the high speed signal to meet any additional requirements as to movements of trains at such points.

It will be seen from the above that the mental operations which the high speed runner would be obliged to carry out are limited to not more than four at the instant that he observes the signal, his rule being :

1° Stop if a red light or a horizontal blade is displayed;
2° Run if a green light or vertical blade is displayed;
3° Reduce speed as is necessary if a red and green light is displayed, or the blade is pointing 45° upwardly;
4° Reduce speed if a yellow light is displayed or the blade is pointing 45° downward.

Having got his train under control, he then has ample time to further consider the movements which correspond with the kind of signal and with the location on the road. The diagram given hereafter illustrates the system as proposed by the Railway Signal Association and that suggested by your reporter.

As a matter of information in connection with the use of interlocking and block signals in the United States, the following statement will prove most interesting.

During the last two years, a wave of legislation has passed over the United States having for its aim the compulsory use of electric head lights on locomotives and, although the Railway managements presented the strongest arguments against such a requirement, many of the states passed the bill and made it a law.

There is no doubt but that the use of the electric head light largely diminishes the distinctive character of night indications of block and interlocked signals. On lines of single track the condition will be serious enough but where there are two or more main running tracks the electric light blinds the runner of an approaching train on an adjoining track so that for an appreciable time after having met the train the eye cannot tell one colored light from another. It is a question still undetermined whether the continued repetition of this blinding effect will not seriously impair the vision and thus reduce the period of the runners safe employement on lines where the highest speed trains are guided wholly by block and interlocked signals. While there is no chance for a repeal of this law for one or two years in those states where it has been adopted it is hoped that other states will not follow their example and that experience will lead in due time to the elimination of this unfortunate and even dangerous legal requirement.

Summarizing the situation as regards interlocking in America:

Application of power interlocking is rapidly increasing;

Electro-pneumatic and purely electric systems are superseding all other forms of power interlocking;

The track circuit, with electric locking, is superseding mechanical detector bars;

All forms of electric locking are being generally used in connection with heavily worked terminals and in heavy traffic territories;

Diagrams for facilitating the full utilization of tracks along passenger platforms are not used in the United States.

REPORT N° 2

(Holland)

By L. H. N. DUFOUR,

ENGINEER TO THE COMPANY FOR WORKING THE NETHERLANDS STATE RAILWAYS.

SECTION A.

CHAPTER I.

The operation of points and signals by hand levers.

a) Introduction.

The signalling arrangements on the Netherlands Railways conform to the bye-laws and regulations of 1875. These regulations require that stations, junctions and swing-bridges should be protected by signals placed at about 300 metres (328 yards) in advance of them. The setting of the signals protecting a station should be under the control of the station-master. The signals which protect swing-bridges should be interlocked with the mechanism for wedging and locking the bridge.

Except in such cases as have been passed as exceptional by the Minister of Railways, the position of the points is shown by a signal.

Although these bye-laws and regulations only require simple appliances, the Dutch Railway Companies, profiting by the experience of neighbouring countries,

*

have not failed to improve their signalling systems, so that on all leading railways we now find the points interlocked with the signals and the operating gear usually centralized.

The Dutch Railways are worked : *a*) by the Company for working the Netherlands State Railways (hereinafter designated by the letters N. S. R., about 1,800 kilometres [1,120 miles]) ; *b*) by the Holland Railway Company (H. R.), about 1,300 kilometres [800 miles]); *c*) by the Central Netherlands Railways Company (C. N.), and by that of Boxtel-Wesel (B. W.), each of which only works about 100 kilometres (62 miles).

There is a considerable difference between the signalling systems employed and also between the apparatus used on the N. S. R. and on the H. R., but the C. N. and B. W. Companies use apparatus of the type used on the N. S. R.

According to the bye-laws and regulations, the signalling system in use before 1883 consisted only of distant disk signals worked on the single-wire system, by means of levers placed some near the station offices and some near the outermost points.

In some stations, the distant signal levers worked from the cabin at the outermost points were blocked by the signalman and unblocked by the station-master by means of the Siemens & Halske apparatus. The German firm had been entrusted with the complete installation of the first sets of apparatus, and had at the same time replaced the distant disks of French origin by semaphore masts with lifting arms of the German pattern.

At some of the junctions, a more complex apparatus, of English origin, was in use : the points were operated by rodding, and the signals by single-wires.

To effect an economy in the staff, and on the initiative of Mr. van Hasselt of the H. R., Mr. Taurel, the Engineer of this Company, constructed and installed in 1883 double-wire apparatus of strong construction for the operation of points at long distances (400 metres [437 yards]). These appliances, described in the *Revue générale des chemins de fer* (1), are the predecessors of all centralized systems of wire-operated apparatus used in the Netherlands.

The appliances for operating and bolting the points, the signals and the transmission gear, have been considerably modified since this date. The general principles of the construction and the use of a wire-transmission, without special arrangements for compensation for variation in temperature, have nevertheless been retained.

Centralization effected by means of rodding has been entirely abolished; the cost of up-keep was enormous in comparison with that of the wire-transmission. It was, moreover, difficult to maintain the rodding in good working order, and to be sure that the points were brought home against the stock-rails in the marshy and shifting lands of Holland. The operation of the signals by single-wire caused so

(1) No. 4 of 1886, p. 217.

much trouble that is was replaced by the double-wire system, even in the case of the English apparatus many years before this latter was abolished.

The general form adopted for the protecting signal was the semaphore with a straight lifting arm. This arm terminates in a semi-circle of radius equal to the width of the arm. The stop signals are situated 300 metres (328 yards) in advance of the danger point, in those cases in which there is no distant signal. When the stop signal is preceded by a distant signal, distant 450 to 500 metres (490 to 546 yards) from it, the stop signal is placed 100 metres (109 yards) from the danger point on the N. S. R. and 150 metres (164 yards) from the danger points on the H. R.

On the H. R. all points are provided with a ground-signal with lantern, of small size, whereas on the N. S. R. a signal is only used at the outermost points; this has a height of 3·20 metres (10 ft. 6 in.). It shows by a rectangular arm measuring 950 × 340 millimetres (3 ft. 1 $^3/_8$ in. × 1 ft. 1 $^3/_8$ in.), and by a white light, that the points are set for the main line and by a circular disk 750 millimetres (2 ft. 5 $^1/_2$ in.) in diameter, and by a green light, that the points are set for the branch line.

The N. S. R. scarcely ever uses a distant signal with two arms to show the different tracks leading into a station, but considers a home signal at the station and a clearly visible signal at the outermost points sufficient indication for the purposes of the drivers; the H. R. frequently uses candelabra posts, with two masts, each fitted with an arm, the top arm relating to the main line and the other to the branch line.

When the signals at the entrance to a station are not easily visible, and on lines with heavy traffic, the signals at the entrance to the station are preceded by distant signals.

The distant signal consists of a caution semaphore-arm placed at a height of about 9 metres (29 ft. 6 in.), with the end of the arm cut off square. This arm, which is inclined at 45° downwards (or shows a green light at night), requires slacking, whereas, when inclined 45° upwards (or showing a white light at night), gives " line clear ".

The signals which are situated between the outermost points of a station on the N. S. R. are not generally preceded by distant signals. The instructions require that signalmen should only give the " line clear " signal on distant signals under those conditions when the succeeding stop signals at a distance of about 800 metres (875 yards) are also set to " line clear ", or after having ascertained that the train has slacked or has stopped before the distant signal.

When the atmospheric conditions prevent the signals from being seen, the signalman must ascertain the position of the succeeding signal by means of the telephone.

The H. R. does not follow this rule, and has extended the use of distant signals at stations.

On the H. R. the signals at the entrance to a station and the signals protecting junctions, swing-bridges, etc., are preceded by a fixed optical indicator called a

beacon, placed 850 metres (930 yards) in advance. This indicator consists of a plate 1·50 metres (4 ft. 11 in.) in height, and 0·75 metre (2 ft. 5 1/2 in.) in width, painted in black and with chequer pattern and placed against a post having a height of 2·50 metres (7 ft. 4 5/8 in.). This indicator serves to notify the driver of the train that he is approaching the signals particularly in the case of fog.

The same reason has led the N. S. R. to place attention boards (beacons) on some of their lines in advance of the home signals; these attention boards consist of three planks about 5 metres (16 ft. 5 in.) in length; they are painted white, are slightly inclined, are spaced about 10 metres (32 ft. 10 in.) apart and are placed at a height which increases from 1·50 metres to 3 metres (4 ft. 11 in. to 9 ft. 10 in.) above the rail level (1).

The small stations on the N. S. R. and on the H. R., which have two or three crossings, or passing loops in the case of single-tracks, are now nearly all fitted with a lever frame, arranged near the station offices. The apparatus consists usually of four or six levers connected to the outermost points and to the stopping signals. The settings of the intermediate points which give access to the goods bays and sidings are determined by locks, the keys to which are interlocked with the lever frame on the N. S. R. or by means of point bolts on the H. R.

The distance between the outermost points and the hand lever is sometimes as much as 550 metres (600 yards); the position of the points, worked at a great distance from the frame, is confirmed by a bolt (detector) inserted in the connections to the signal.

So soon as the traffic on a single track becomes fairly heavy, each of these companies provides starting signals, in some cases a signal for each track by which a train can leave.

Those single tracks on which fast trains are run have been fitted in recent years with single-track block apparatus on the Siemens & Halske system; in this case, the starting signals are interlocked with the block apparatus. A combination which is analogous to the starting signals and electric block apparatus is very frequently provided on the N. S. R.; this makes the setting of the starting signals dependent on certain appliances situated on the track, such as the wedging gear of swing-bridges, points giving access to sand-pits, loading sidings, etc.

The signalling arrangements and frames at small stations, which we have just described, have some disadvantages : 1° in the event of error being made by the station-master a train can enter on a line already occupied by another train; 2° at stations where trains pass each other it is almost impossible to verify whether the

(1) Special precautions are taken, moreover, in time of fog. The trains are kept further apart so that they are separated by at least one block section. Detonators are placed in advance of or near to, the signals by employees specially chosen for this duty. Telegraph or telephone messages are exchanged relating to the positions of swing-bridges, etc.

whole of a train entering the station has arrived (without any breaking away) before permitting the departure of a train in the opposite direction; 3° the operation of points situated at a distance greater than 200 metres (219 yards) from the frame presents certain difficulties.

The first disadvantage can be overcome by electrically insulating one of the station tracks and employing a gear which prevents the home signal being put to " line clear " when the track ceases to be insulated; the H. R. has installed such arrangements in some stations; these will be described further on (see appendix V).

This disadvantage may also be to some extent avoided by interlocking the starting signal for each road with the home signal for trains arriving from the opposite direction. The interlocking of the hand levers operating these signals must satisfy the following conditions: 1° the home signal A, permitting arrival on the road *a*, can only be set to " line clear " when the home signal B, and the starting signal C, for trains arriving from the opposite direction, on the same track *a*, are at danger; 2° after the home signal B has been again set to " danger ", it is impossible to pull off the signal A, until after the starting signal C has been pulled off and again set to " danger ". The N. S. R. have adopted this method in several stations.

It is impossible to avoid the second disadvantage without installing special cabins at the outermost points.

To obviate the third disadvantage, we have had some appliances arranged with a key, which enabled the points to be disconnected from the transmission gear when the lever was in a certain position, so that the points could be operated at the spot. These appliances did not come up to expectation; the staff preferred to operate the points from a distance to avoid the constraint and running about which always accompany these combinations.

In the case of more important stations, as well as on stations with direct access to sidings on double-tracks where the points are taken facing, centralisation in a single frame placed near the station offices is but rarely employed, because as the distance between the points becomes greater and greater, there is a corresponding increase in the disadvantages already enumerated.

Although the cost of the installation is greater and although the staff required is more numerous, a cabin has been erected at each end of the station. When it is not desired to fit insulated track sections, it is found that the traffic can be worked better when the necessary operations for authorising a train to pass are divided between two people. These two employees can keep a check on each other.

Moreover, the signalman in cabins at the ends of the station can ascertain whether the whole of a train (without breaking away) has entered a loop; this is an impossibility in the case of the employee situated at the centre of a station.

The wood or brickwork cabins, with the floor at a level of 2 metres (6 ft. 6 3/4 in.) above the rails, in this case contain a frame with levers for operating the points, the home and distant signals and the starting signals. The signal levers are interlocked by means of the electric apparatus of the block-system.

On the N. S. R., the two cabins A and B have these block-instruments slotted direct with each other, whereas the H. R. has inserted the block apparatus in the station-master's office between the block instruments of the outer cabins.

On the N. S. R. the signalman at cabin A demands, by means of an alarm, of the signalman in cabin B, road clear for a train proceeding from A to B; the signalman at B gives him " line clear " on the track corresponding to that demanded on the electric block-apparatus, and the signalman at A can only pull off his home signal when his points have been set to make the road cleared by cabin B.

For trains proceeding in the opposite direction, the signalman at A similarly gives " line clear " to the signalman in cabin B; of course the block instruments are inter-connected in such manner that it is impossible for both to put their home signals to " line clear " for the same track.

One of the cabins is considered the chief cabin; this cabin is fitted with telegraph apparatus giving comunication with the other telegraph station on the line. In case changes in the train service are necessary, the employee in the chief cabin notifies the station-master by telephone and informs the signalman in the second cabin.

The electric block-system apparatus for the main line is fitted in the outer cabins in such manner that the signalman are in direct communication with the adjacent cabins; this block-apparatus is generally connected to the block-apparatus at the station. On the H. R. the block-system for the main line is operated from the stations-master's office; the stations-master gives " road clear " for a train arriving at his station on any given track, and he also gives " road clear " for the departure of this train. He is in telephonic communication with the cabins on the main line; the signalmen are, therefore, completely under his control.

On the N. S. R., in some cases, one of the cabins is placed near the station offices and one of the employees in this office fulfils the functions of signalman; as a rule, there are always two employees who must act in agreement with each other to effect the necessary manœuvres for the working of the traffic.

To secure an economy in the staff, the site of the cabins is selected, whenever possible, near to a level crossing, even though the points may be 250 metres (273 yards) distant; the barriers at the level crossing are worked by the signalman.

On the N. S. R. the block-apparatus on the main line stands normally at " line blocked "; that is to say, a signalman cannot pull off his signal till after the road has been cleared from the succeeding cabin in reply to a demand made by means of the electric alarm. This cabin cannot give " line clear " to the preceeding cabin unless he has blocked the line in the rear of the last train.

On some lines of the N. S. R., as on all the lines of the H. R., the system of " line normally clear " is still to be found, although the signals stand normally at danger; the signalman can set his signal to " line clear " provided he is not blocked for a train on the succeeding section of the track.

The N. S. R. has preferred the system of " line normally blocked ", although the expenses are relatively greater.

1° For enabling the unblocking to be operated over a second section and thus to increase the distance between the trains in time of fog;

2° For enabling the signalman to allow shunting operations to be performed with safety on the section of the main arrival line in advance of the home signal; the signalman can protect such operations by keeping the line blocked to the preceding station.

In stations covering a large area, large cabins with a great number of levers are frequently found. There is no objection to operating points at a distance of 400 to 500 metres (437 to 547 yards) from such cabins, when these are only used by the regular traffic and when they are but seldom employed in shunting operations. A distance of 250 metres (273 yards should not be exceeded in the case of points which are frequently used by such trains. The difficulties which arise when this distance is exceeded may be met by fitting an alarm push-button near the points; by means of this alarm the making of the road can be demanded of the signalman.

As usual, all the passenger tracks in stations are used for all roads on the N. S. R. as well as on the H. R.; frames exist which contain sixty to seventy levers, with a large number of small hand route-levers; it follows that the length of the frame may sometimes exceed 10 metres (32 ft. 10 in.).

It is almost always desirable that the floor of the cabin should be placed at a considerable height; this height varies from 4·50 metres to 7·50 metres (14 ft. 9 in. to 24 ft. 7 in.) in the large cabins on the N. S. R.; the preliminary erection of a scaffold to determine the best situation and the most suitable height for the cabin has given good results.

In some cabins, hot water heating has been applied with success.

On the N. S. R., in the zone of operations of the cabin, the tracks are protected by semaphores against trains arriving by main lines and by disks against trains arriving from branches; these signals apply to the drivers of the regular trains, and also to those performing shunting operations. The drivers of trains on starting must notice, in addition to these signals, the starting signals at the end of the station giving the road.

By employing the fixed signals for shunting operations, the trains and locomotives can run through the station at a higher speed than would be possible if point indicators and portable signals were used.

The traffic on passenger tracks, and on the chief goods roads between the two cabins, is controlled by signals. Their position depends always on the positions of two levers in the two cabins, or else the lever in one cabin is slotted by the other cabin through the intervention of an electric block station apparatus. In the case of the other tracks, permission, given by telephone, must precede the arrival of the train in the zone of the cabin.

The block signal on the main line consists of a semaphore placed about 50 metres (54 yards) beyond the outermost points (1). This signal may also serve to give the road.

On the H. R., on which the signals only control the regular train service, the system of special signals for shunting has been greatly extended. These signals consist of a pair of arms at the top of a post: if the two arms are placed at right angles to the direction of the tracks, and if a violet light shows at night, shunting operations may be performed, but if the two arms are parallel to the direction of the tracks and the light is not visible, shunting operations may not be performed.

Whereas on the H. R. all the necessary measures are taken for the arrival and clearing of the trains from the central cabin, the central cabin on the N. S. R. only deals with ordinary trains entering its zone, and with goods trains which in entering or leaving may hinder the working; thus the signalling on the H. R. is, as in Germany, more centralized in the hands of a single employee. The N. S. R. system resembles more closely the English or Belgian systems, which give more freedom to the signalman. In both systems the chief responsibility, which consists in ascertaining whether the roads are clear or blocked, rests with the same employees. In the German system of the H. R., the operator in the central cabin can only ascertain whether the roads are clear or blocked by the aid of the signalman.

b) Lever frames.

The apparatus for operating the signals and points in the Netherlands at the present time, may be divided into three classes. Class No. 1 which is of fairly simple and strong construction does not lend itself well to combination with the block apparatus, whereas classes No. 2 and No. 3 allow this apparatus to be so fitted that the levers are controlled by an electric slot system.

The strong construction of class No. 1, as well as the simplicity of its parts, permits of its being fitted in the open. The locking bars being only six in number, it does not lend itself well to the arrangement of a large number of interlocked levers.

The apparatus consists of a certain number of pulleys, each carrying its lever, and turning about a common axis. The rim of the pulley is grooved, and the chain which forms a portion of the wire-transmission, is fastened in this groove. In its normal position, the lever is thrown back and stands at an angle of 20° to the vertical; when pulled over the lever is horizontal; in operating the lever, the hand moves through a distance of 1·50 metres (4 ft. 11 in.), corresponding to an angle of 110° moved through by the pulley and to 500 millimetres (1 ft. 7 $^{11}/_{16}$ in.) travel of the chain.

---

(1) Vide *Bulletin of the Railway Congress*, No. 8, August, 1908, p. 843.

The pulley shaft is carried on pedestals; there is one pedestal at each end and an intermediate one after the fourth, eighth and twelfth pulleys; the apparatus is never used for more than sixteen levers.

The details of the apparatus were described in the *Bulletin of the International Railway Congress* (1).

The lever apparatus of class No. 2, generally in use on the N. S. R., is of the Siemens & Halske pattern; the appliances are constructed either in Berlin or at Alkmaar, near Amsterdam.

The frame, the length of which depends on the number of hand levers, is carried on two supports when the number of levers does not exceed twenty-one and the length is not over 2,300 millimetres (7 ft. 6 9/16 in.).

For a greater number of levers, the frames are placed against each other; the interlocking bars of the different frames are joined by connecting pieces.

We give, further on (appendix I) a description of these appliances.

The lever frames of class No. 3, in general use on the H. R., are manufactured by the " Alkmaarsche Yzergietery " at Alkmaar. They are described in appendix II.

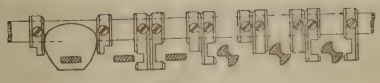

Fig. 1.

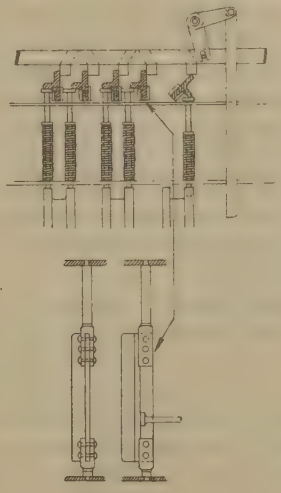

Fig. 2.

The interlocking arrangements in apparatus of classes No. 2 and No. 3 consist of shafts which carry tappets acting, between the bars, on pins fixed on one side of the bars; in large frames, this gives rise to much difficulty when any modification

(1) Vide *Bulletin of the Railway Congress*, No. 10, October, 1908, p. 1105,

is required. In order to fit or to remove tappets on any shaft, the whole of the bars and the shaft affected have to be taken down. This operation is difficult, and it is dangerous to perform it while there is traffic; for this reason, in the Siemens & Halske apparatus of recent construction as well as in the Alkmaar apparatus, the shafts are replaced by rocking bars of special section which act on tappets bolted or screwed to the bars.

Figure 1 shows diagramatically the new mechanical interlocking gear in the Siemens & Halske apparatus, and figure 2 shows a similar method applied in the Alkmaar apparatus.

Its is interesting to note that these methods are very closely similar to those adopted by Messrs. Saxby & Farmer over thirty years ago.

c) Appliances for operating and bolting the points.

On the N. S. R. and on the H. R., prior to 1895, the point-tongues, in the case of points operated from a frame, were connected to each other by two or three rods; the movement of the parallelogram formed by the tongues and rods was effected by the rotation of a specially formed cam. This cam was carried on a vertical axis, and was of the shape of two circular arcs having the same centre but unequal radii; the two circular arcs were connected by suitable transition curves. The rotation of the cam gave a to-and-fro movement to the crossbar connecting the point-tongues.

The movement of the apparatus may be divided into three periods corresponding respectively to successive angles of 45°, 120° and 45° of rotation of the pulley. In the first period unbolting is effected; during the second period (of 120°), the disk acts on rollers and the point-tongues are thrown over; the bolting of the points is effected during the third period.

The apparatus of the N. S. R., of which over 800 are still in use was described in the *Revue générale des chemins de fer* (1).

To avoid damage occurring to points fitted with this apparatus in the event of running through from the trailing side when wrongly set, the crossbar was weakened in the centre, so that it bent or broke at this part.

This arrangement has a well-known disadvantage, which can be to some extent overcome by the use of fixed signals on all the roads made by the points in question and by the use of bolt-locks connected to the signal transmission gear.

In more recent installations, it has been preferred to fit shunting points of German origin; in these, the point-tongue which is pressed against the rail is bolted, while the other tongue, although connected to the operating and the transmission gears, is, in the case under consideration, free to follow the action of the wheels by disconnecting the pulley from the operating lever in the central frame.

---

(1) January 1891, p. 30.

Nevertheless the N. S. R. and the H. R. prefer the type which cannot be run through trailing when wrongly set at places where running through is unlikely; for example where no shunting operations are carried on, at junctions, etc.

We are of opinion that a system with rigid point-tongues is preferable when it can be applied without disadvantage. In nearly all the points, one of the tongues guides the wheel while running on a curve, and it is certain that this tongue can better resist the forces acting on it if it is locked, as in the old appliances, than when it is free, as in the new.

By acting as a check-rail, the tongue is subjected to shocks as each wheel passes, and these blows, although transmitted through the point gear and transmission gear, produce rather rapid wear of the operating gear.

The appliances used for operating points in Holland are described in appendix III.

d) Flexible-tongue points on the H. R.

The H. R. is, at the present moment, fitting points on its main lines in which the point-tongues are of planed rail and are fished to the succeeding rail length; they are also firmly connected by cross-stays with the stock-rail over a portion of their length. This point-tongue is moved, not by pivoting on its heel, but by bending over a part of its length which is planed on both sides of the sole. The point-tongue bears against the stock-rail when it is free. To move one of the point-tongues to make a road, it is necessary that the tongue which is drawn back must be acted on by a force. When fully drawn back, it acts as a spring and tends to return to its normal position.

When points which may be run through trailing while wrongly set are fitted with these tongues, the gear is subjected to the action of this force which tends to move it bodily. This form of construction can only be allowed to be used when precautions are taken against the effect of this force.

The H. R. has adopted an arrangement shown in figure 3. It consists of a system of spiral springs A, placed between the tongues and connected to levers which are pivoted at one end on pins C, carried from the sleepers.

The other ends of these levers are connected to the tongues by rods D. The ends of the springs slide in the slotted holes formed in the levers; the system of rods, levers and springs is so arranged that the springs only act on the tongue which is drawn back. The action of the spring thus compensates the force referred to.

For actuating the flexible tongue-points the H. R. sometimes employs a well-known German system which can be readily understood from the drawing (fig. 3).

e) Signals.

The semaphores on the N. S. R. are made of steel plate; the arm, which is of iron or of aluminium for distant signals, is placed at a height of about 9·50 metres

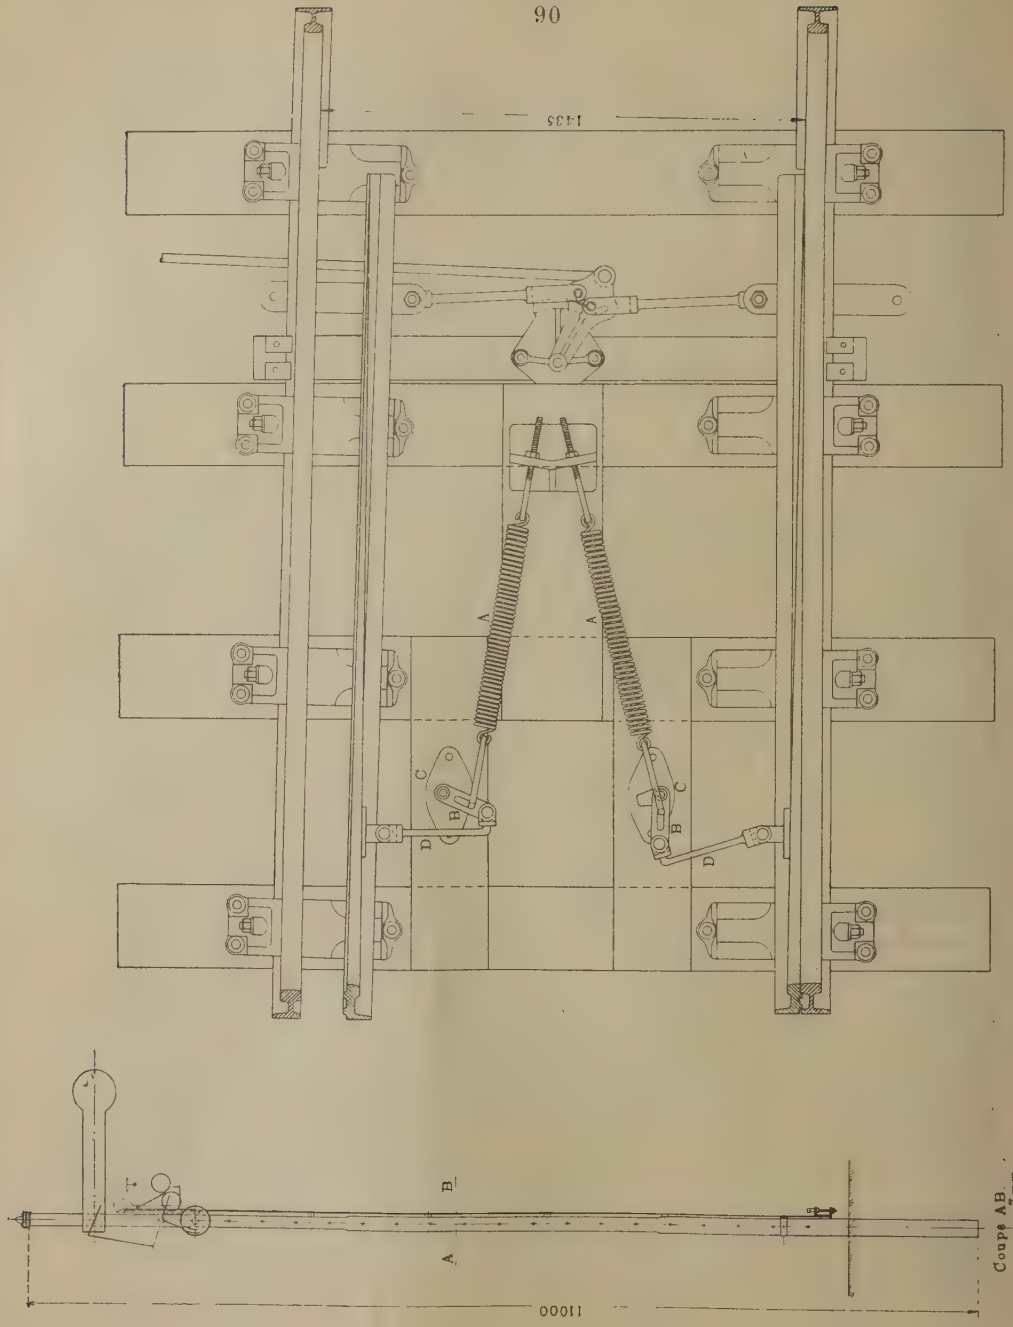

Fig. 3.

(31 ft. 2 in.) above the ground level. The arm is operated by means of a slotted lever actuated by a chain pulley; the construction of the semaphore has been described inthe *Bulletin of the International Railway Congress* (1).

The steel plates rust on the inside where the conical tubes are inserted into each other. Water of condensation deposited on the inner edges assists the corrosion.

The life of the semaphore masts does not generally exceed twenty years.

In recent years, semaphores have been adopted in which the mast consists of a Mannesmann tube, shown in figure 4; it is hoped that this will give longer life to these signals.

The greater number of the signals are lighted by means of paraffin lamps; during the last few years, the nickel reflectors of these lamps have been replaced by glass lenses giving better concentration to the light with reduction in the first cost and in maintenance. In stations fitted with electric light, incandescent lamps (of 10 candle power and with a lens, have been in use for upwards of ten years for the station signals; the paraffin lamps have, however, been retained for the home and distant signals.

Normal incandescent 10 candle power lamps have been used successfully: they are placed in parallel across the main cables laid for the purpose. The use of electricity has effected a considerable saving both in respect to the staff required for lighting up and in maintenance.

The semaphore signals of the H. R. are nearly the same in construction as the signals of the N. S. R. A difference exists in that one of the coloured glasses is placed in a hole cut out of the arm and that the other is carried in a frame connected to the angle iron edges of the arm. The movable platform for the lamp carries a shutter which cuts off the light of the lantern until it has been elevated to the correct height.

f) Transmission gear.

In the article in the *Bulletin* just quoted, we have described the wire-transmission in which a steel wire 5 millimetres (0·197 inch) in diameter is used for operating the points and of 4 millimetres (0·157 inch) in diameter for operating the signals; No. 11 of the *Bulletin* for 1908 contains a description of transmission by wires laid in tubes filled with oil; this method is frequently adopted on the N. S. R. for crossing under canals and under the sleepers of the tracks.

The transmission gear is not fitted with arrangements for locking the apparatus operating the points in case of the breakage of the wire.

Being of good material, the galvanised steel wires only break when they have become reduced in size by oxidisation; they should then be renewed.

---

(1) Vide *Bulletin of the Railway Congress*, No. 10, October, 1903, p. 1105.

The use of safety apparatus to act in case of fracture of the wire is not required by breaking of the wire itself, but by the fracture of the joints and through the serving giving way.

When the joints are well soldered and varnished, when welded chains are used on the pulleys instead of served wire, and when the gear is efficiently maintained, it has not been found necessary to use such apparatus which complicates the installation.

In the case of the distant signals, the slot lever gear is so arranged that the arm goes to danger in case of rupture of the wire; the working of this gear, however, is not positive, particularly when a transmission gear of some length is altered frequently after it has been installed.

g) Compensating gear.

Compensating gear for maintaining a uniform tension in the wires is only used when the length of the transmission exceeds 900 metres (984 yards) and it is situated on a curve.

The N. S. R. in such cases uses the "Marissen" oscillating compensator described in appendix IV.

No compensating gear is used in the transmission to points, even though these be situated at a distance of 550 metres (600 yards). In the case of facing points distant more than 250 metres (273 yards) from the cabin, bolt-locks are fitted. The N. S R. also uses bolts for main line points when the distance is shorter and when there is no difficulty in fitting them.

h) Bolt-locks for points (detectors).

On the N.S.R. in general only one, two or three bolt-locks on the straight are fitted to a signal wire. Only very rarely is a wire deviated from its direct line for the purpose of fitting a bolt. In such cases, if the points are of such importance as to require a bolt-lock, it is preferred to operate this by a special lever.

The detector-bolts shown in figures 5, 6 and 7, consist of a bar T-iron inserted in the transmission to the signal; this T-bar is guided between plates, slides in cast-iron guide-blocks and locks the bars, A and A', connected to the points. When the signal is at " line clear " the T-bar does not hold the bars, A and A', and consequently the points. The object of the bolts is only to verify the position of the points; as the points should be capable of being taken from the trailing side when wrongly set, the construction enables the signal to be reset to danger because the notched blade of the T-bar can be displaceda bove the bars A and A'. This displacement is possible because the guide-plate B can lift with the T-bar against the tension of the springs by which it is held to the cast iron guide block.

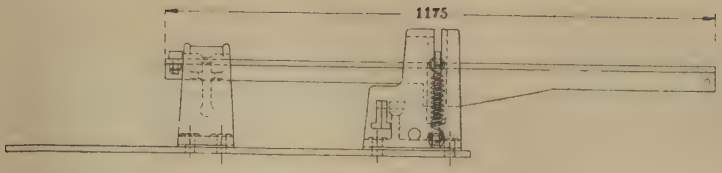

Fig. 5.

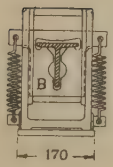

Fig. 7.

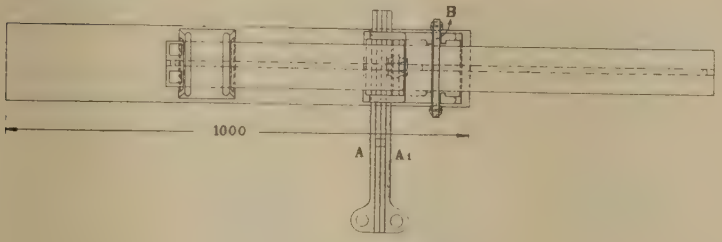

Fig. 6.

The H. R. applies bolts of the construction shown in figures 8 and 9, giving a slight resistance to movement; it does not appear necessary to describe these bolts.

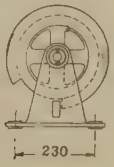

Fig. 8.

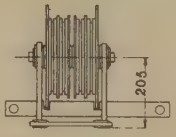

Fig. 9.

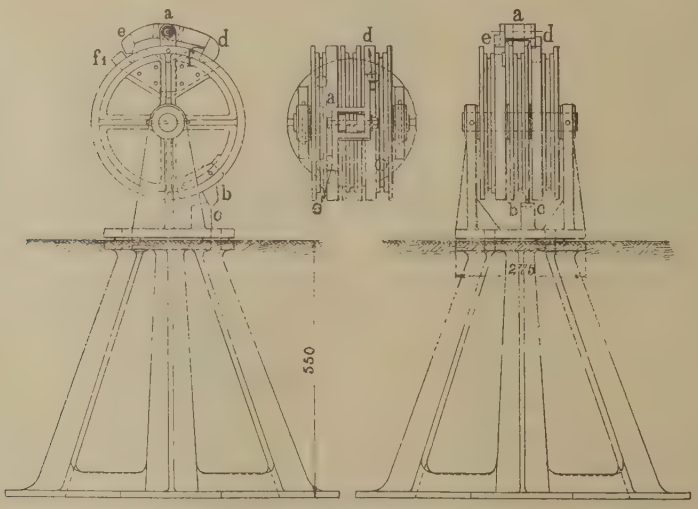
Bolts which allow the points to be taken trailing when wrongly set are generally made for insertion in the distant signal transmission and are connected to the outermost points at small stations where they are operated from alongside the station buildings. When there is no starting signal, it is possible for the train to be started without putting the distant signal to danger. In this case, a bolt which did not permit running through trailing would suffer damage, and it is almost certain that the operation of the distant signal having been rendered impossible, the arm will stand at " line clear ". The train following may, therefore, find the points wrongly set and the signal corresponding to the correct road standing at " line clear ". With a bolt arranged for running through trailing, the signal can always be put to danger, whereas the bolt bars prevent the signal being pulled off, since they never return to their original position after the points have been taken trailing.

i) Slotted gear.

Slot gear inserted in the wire transmission is used as shown in figures 10, 11 and 12, with the object of making the position of a signal simultaneously dependent on two cabins. These appliances consist of a system of three pulleys all turning on the same shaft.

The two outer pulleys are connected to the two hand-levers, whereas the centre pulley is connected to the signal. This latter pulley carries a movable shaft of special form fitted on each side with a ratchet-lever; one of these ratchets slides on the edge of the right-hand pulley or enters into the notch in it, whereas the other ratchet occupies similar positions in respect to the left-hand pulley.

Fig. 10. Fig. 11. Plan. Fig. 12.



Figs. 10 to 12.

When the levers are in their normal position, the stop *b*, fixed to the centre pulley, meets the finger *c*, on the pulley frame, while the ratchets are opposite the notches in the pulley or partially entered therein.

In operating the left-hand pulley the corresponding ratchet *d*, which is of wedge shape, is raised; this ratchet, sliding on the rim of the pulley, engages the ratchet *e* with the right-hand pulley. It thus locks the right-hand pulley to the centre pulley.

In operating the first pulley, nothing is done except to place the ratchets in position so that, on operating the second pulley, the centre pulley connected to the signal is rotated.

In setting one of the outer pulleys to its normal position, the middle pulley connected to the signal is always driven by means of the tappets f and f', which engage the ratchets in this direction of rotation.

The slot mechanism is sometimes constructed of other form : When fitted on the semaphore masts, the centre pulley may be replaced by a simple crank arm connected direct to the semaphore arm.

j) The use of insulated rail sections on the H. R.

In many stations, the H. R. uses electric apparatus consisting of track circuits to prevent the authorisation of the arrival of a train on a road already occupied. Appendix V gives a description of the working of these appliances.

CHAPTER II.

The use of water, compressed air and electricity for transmission.

The railway companies in the Netherlands have, during the last few years, followed the example set by neighbouring countries, and have put some centralised frames at work in which the work of the signalman is assisted by supply of power. The advantages of these installations have been often described; it appears to us unnecessary to enumerate them here.

Trials have only been made in the Netherlands on a very small scale because the question only arises in the case of new installations. In existing installations, a change of system is not under consideration.

The zone of the cabins is already very large, thanks to the use of the double-wire transmission. By this means, the operation of the points and signals can be effected at a great distance, without expenditure of much force, and the radius of action approaches that which can be obtained in practice by means of power distribution.

It should be noted, moreover, that the radius of action does not depend exclusively on the method of transmission, but account must be taken of the situation and of the position of the points, the requirements of the traffic, etc.

One hesitates to employ complicated mechanism in the signalling department for fear of difficulties in the maintenance of the appliances.

Urgent need for making important modifications in the systems in use, which do not merely diminish the hard work of the staff, occurs only when great importance is attached to the permanent control of the appliances, which control is only obtainable by the new systems.

*

Although the importance of this control cannot be questioned, it is doubtful whether it alone justifies the high cost of installation of the new appliances.

For railways on which the traffic is not very heavy or the work very lucrative, it is better to wait until appliances of this type become, like all other artificial mechanical aids, of more general use, of greater simplicity, and of lower cost.

In each of three large stations in which trials were made, only one cabin was fitted with a power supply system. Fortunately the two large companies chose two different systems; whereas the H. R. installed in the cabin at Haarlem station an electro-pneumatic system by the firm of Stahmer, and in one cabin the electric operation of two sets of points and five signals by apparatus coming from the " Allgemeine Electrizitäts-Gesellschaft " of Berlin, the N. S. R. has fitted to a cabin at Rosendaal Station and in the marshalling yard at Maarn, the Siemens & Halske electric system, and has fitted a signal operated by liquid carbonic acid, also made by the same firm.

We can now compare these installations under the same conditions of climate and ground and the Railway Board, who will inspect these, will be able to form an opinion on the relative value of the different systems.

a) Electro-pneumatic installation in Haarlem Station.

The installation at Haarlem Station comprises a cabin with an electro-pneumatic apparatus for operating 25 sets of points with 2 stop tappets, 1 bolt-lock and 4 signals. Appendix VI contains a description of the installation, and figure 13 shows diagramatically the arrangement of the signals.

The central frame for the electro-pneumatic operation is on the Siemens & Halske system. It is exactly similar to the central appliances of the entirely electric installations at Antwerp (see the *Bulletin of the Railway Congress*, August 1904), and of Schwerte (see June and July numbers, 1908).

The construction of apparatus for working the points and signals does not differ much from those of the appliances at Bishopsgate described in the *Bulletin* (1).

At Haarlem, the iron casting containing the slide-valve is placed in an extension of the motor cylinder and not on its side. The bolts of the slide, which are disengaged by a supplementary electro-magnet, and with which the Bishopsgate appliances are fitted, are not used in the new appliances.

The points have a flexible rail for the point-tongue which tends to spring away from the stock-rail. They are fitted with a detector or verifier of the position of the point-tongues. The air pressure on the piston is sufficient to hold the point-tongue against the stock-rail; nevertheless, the points can be taken trailing when wrongly set, without causing damage.

---

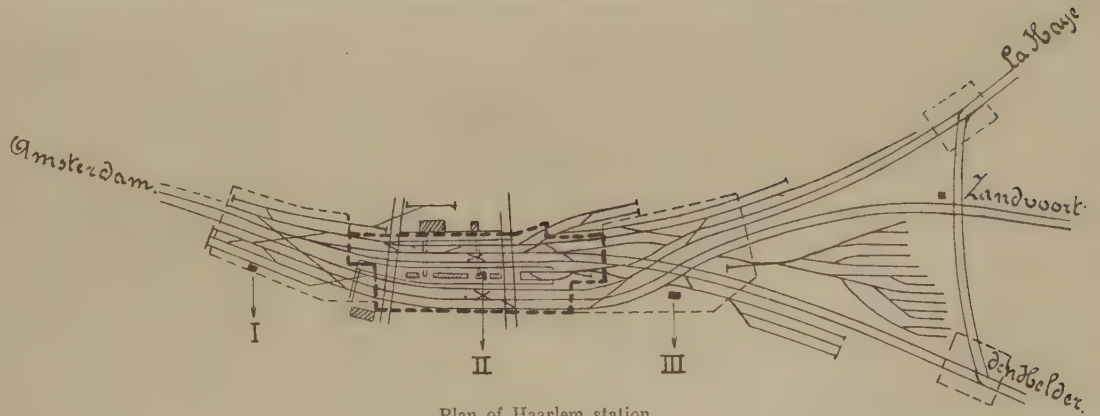
Haarlem station. — Electro-pneumatic transmission to points and signals.



Plan of Haarlem station.

Fig. 13.

Explanation of French terms Cabine II = Cabin II. — La Haye = The Hague.

When points are taken trailing under these conditions, the fact is shown by the detector gear.

The signal arms are fitted with an indicator consisting of a cylinder with metallic segments on which brushes bear, closing or opening the indicator current of the signals.

This indicator current moves the indicators in the apparatus in the signal cabin and shows the position of the signal arm.

The insulated rail sections for preventing premature operation of the points are not fitted on the appliances at Haarlem, although there is nothing to prevent their being fitted and this could be done in the same way as in those installations which are operated electrically.

The plant for compressing and cooling the air is placed in a cellar under the station offices. It consists of a horizontal compressor driven by a 5 kilowatt electric motor by means of a belt-drive. Under normal conditions the motor uses 8 amperes at 440 volts.

The air supplied by the compressor first enters a chamber in which any moisture is deposited, and then passes into two reservoirs each 1 metre (3 ft. $3\,^3/_8$ in.) in diameter and 2 metres (6 ft. $6\,^3/_4$ in.) in height. When the pressure in the reservoirs falls as low as 4·5 atmospheres, the motor starts automatically. It stops when the pressure reaches 6 atmospheres.

The reservoirs are connected by a cooling coil to the main pipes. Experience shows that this coil can be done away with when the intake and air reservoirs are situated in a cold place; the air becomes sufficiently cooled during the period it is stored in the reservoirs. An apparatus for injecting alcohol tends to diminish freezing in the pipes during winter. In case of any defect appearing in the pump or in its motor, the Westinghouse pump on a locomotive can supply compressed air to the reservoirs. Pipes for such temporary supply are arranged in view of the possibility.

To operate the 32 sets of points and signals, about 10 to 15 kilowatt-hours are required par day. In winter the losses of air are less than in summer, because the grease in the stuffing boxes of the motor cylinder becomes thinner as the temperature rises and allows the air to escape.

The consumption of electricity for operating is found on the average to amount te 0·4 kilowatt-hour par lever per day. The indicator current is 0·1 ampere.

Electricity is supplied at 18 volts by nine accumulators, which are charged twice a week for three hours, by a motor-dynamo, giving a current of 40 to 45 amperes at 24 volts. The efficiency of the motor-dynamo being 40 per cent., the indicator current requires 15 kilowatt-hours per week, or from 2 to 3 kilowatt-hours per day.

One must therefore reckon 0·5 kilowatt-hour as the consumption for both operation and indicator per lever per day.

b) Electric operating gear of the points and signals of a junction near Haarlem.

The *Allgemeine Electrizitäts-Gesellschaft* of Berlin has fitted a trial installation for operating five signals and two sets of points at a junction near Haarlem. The apparatus for operating the signals depends upon the use of a solenoid which acts on the signal arm and on an electro-magnet which displaces a stop. This stop serves to lock the operating mechanism while the signal arm is at danger.

The solenoid and the electro-magnet are placed one above the other in a sheet-iron box of a section of 260 × 470 millimetres (10 1/4 inches × 1 ft. 6 1/2 in.), and of a height of 1,050 millimetres (3 ft. 5 3/8 in.). The solenoid has two windings, the one on the upper part and the other on the lower part; its diameter is 250 millimetres (9 13/16 inches) and its height 540 millimetres (1 ft. 9 5/16 in.). It contains a movable cylindrical core with conical ends.

When current flows through one of two windings, the core is attracted in one direction or in the other. The rod connected to the signal arm is attached to a lever, which is moved by the core. A cylinder, the piston of which is immersed in glycerine, serves as a dash-pot.

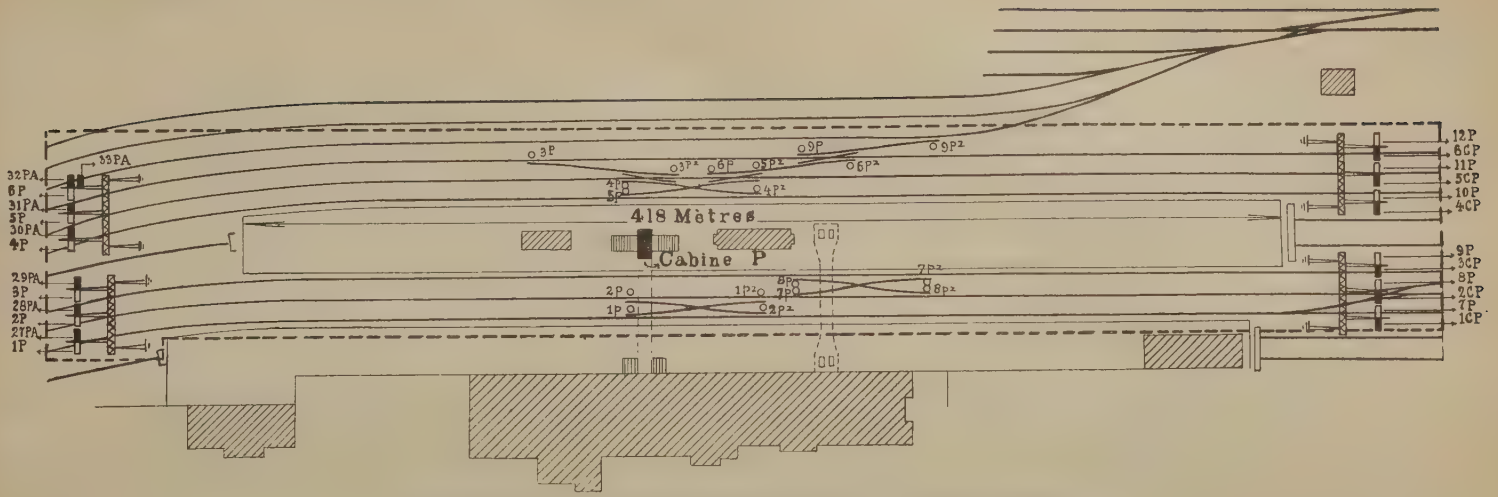
Movement of the core can only occur when the armature of the electro-magnet actuating the stop is attracted by means of the same current. The solenoid and the electro-magnet displace contacts which make the different circuits for operating the signal and the indicator.

A current of 2·6 amperes at 220 volts flowing for two seconds and a half is required to set the signal " line clear ", whereas 2 amperes is sufficient to set it to danger.

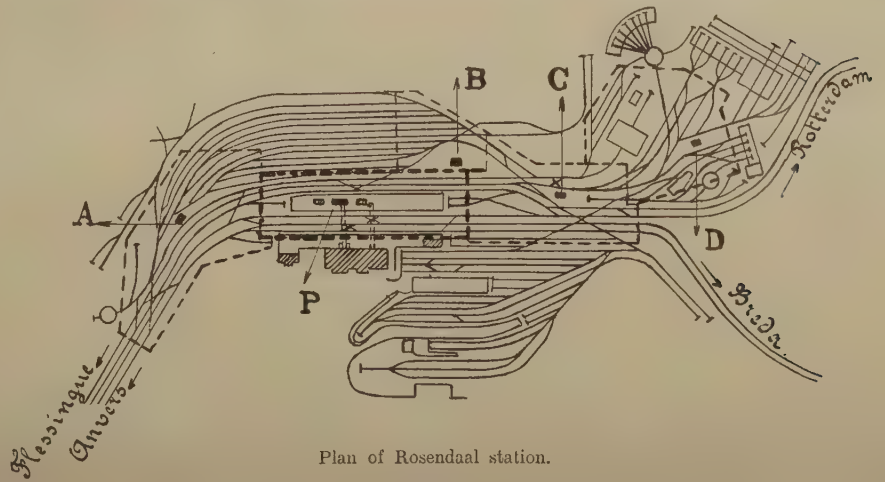
The indicator current, when the signal is set to " line clear " is 0·75 ampere a 220 volts, whereas, in the danger position it only amounts to 0·06 ampere.

In the apparatus for actuating the points, the armature of the electric motor is coupled to an endless screw which acts on a nut; this nut is connected to the point rods which it operates. Indicator contacts show the signalman the exact position occupied by the point-tongues. Untimely operation of the points is prevented electrically by the insertion of a relay to the operating circuit. In the relay circuit, there are three switches placed on the sleepers between the rails. These switches correspond to three other pieces, which are carried on three horizontal arms, fixed to three places on the arrangement of point-tongues and connecting bars.

This system consists of two rails 7 metres (23 feet) long, fished together and to the following rails in the usual manner; tho whole is only secured by screw-spikes of the track. The inside overhangs the upper surface of the sleepers about 5 millimetres (3/16 inch) owing to the action of the flat springs which are placed below the rails and tend to throw them over to the outside. When the train occupies the rails, they are pressed towards the inside ; the sole of the rail bears on the sleepers the arm placed between the rails is inclined, the contact is made, the current put to earth, the relay is attracted and it is impossible to operate the points.



Rosendaal station. — Electro-pneumatic transmission to points and signals.



Plan of Rosendaal station.

Fig. 14.

c) Electric Installation at Rosendaal.

At the Rosendaal station on the N. S. R. the installation comprises 2 central appliances for electrically operating 15 sets of points and 24 signals. The floor of the cabin is only at a height of 60 centimetres (2 feet) above the covered platform. Two appliances have been adopted which are placed opposite to the cabin, in order that the signalman operating the points can see the trains on the tracks alongside the platforms. Appendix VII gives a description of the installation, and figure 14 shows the signal arrangements diagramatically.

The central appliances in cabin P are of the latest type but one by Siemens & Halske, and analogous to those in Haarlem Station. Electric cables with 5 wires connect the central appliances to the points and to the signals. The apparatus for operating the points and signals has been described in the *Bulletin of the Railway Congress* (1). The appliances for operating the points are fixed to a frame of angle-iron, which embraces the rails at the points.

Figure 15 shows the apparatus connected to a jointed wedge arrangement constructed for running through trailing when wrongly set, made by Schnabel & Henning, such as is in use on the N. S. R.

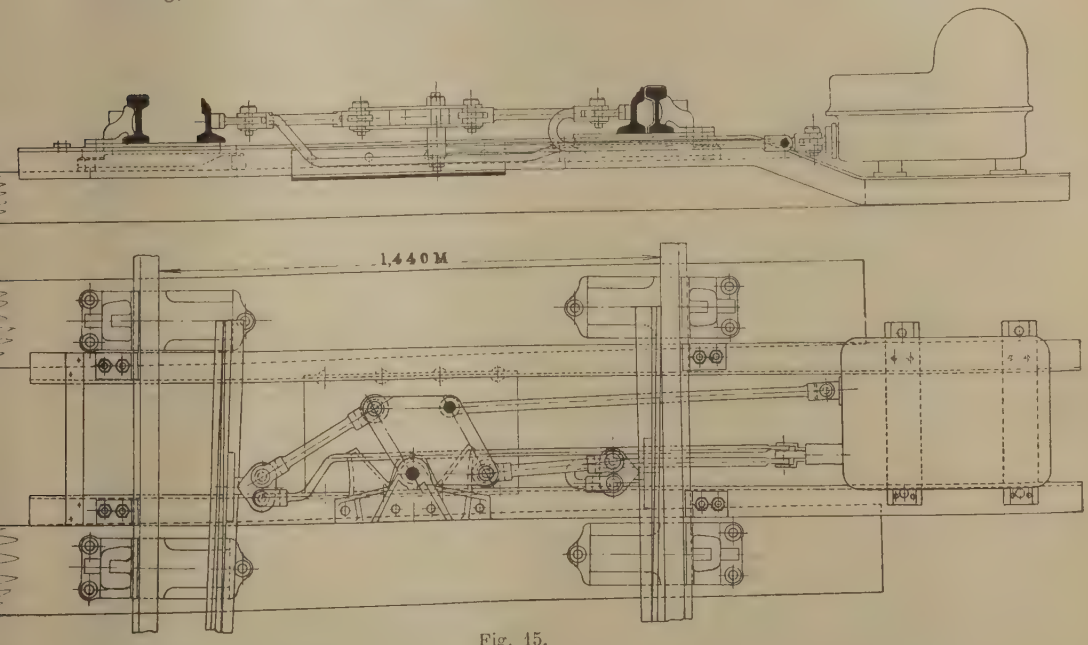


Fig. 15.

(1) Vide number of August, 1904.

Signals which are shown by two letters, for example, AP in figure 14, are actuated from the two cabins A and P. The signal has only one motor; the working and coupling circuits going from cabin P to the signal are controlled by contacts made or broken by operating the corresponding levers in cabin A on the hand-lever frame.

Signals with two arms have only one motor; a selector gear connects the motor to either of the arms.

The point-tongues on main lines are fitted with indicator contacts showing the position of the tongues.

These arrangements, as well as those for operating two sets of points with a single lever, and those for locking the points while any vehicle is on them, are installed in the same manner as in the Antwerp station.

The N. S. R. has no flexible-tongue points in use, as on the H. R. It seems that this type of point-tongues has some disadvantages when applied to normal electrically operated points. The apparatus and the motor can turn partially under the pull of the point-tongue in its sprung position.

To overcome this difficulty, the firm of Siemens & Halske, in their last catalogue, have described an apparatus with a spring wedge which engages with the connecting crossbar and prevents dangerous displacement.

On the N.S.R., at Maarn and Rosendaal, electricity is supplied by three accumulator batteries of 72 cells of a capacity of 27 ampere-hours and of 9 amperes discharge current. During the charging operation of one of the batteries of 72 cells by connecting it through a commutating resistance to the lighting circuit at 220 volts, the second battery can be used for the electric operation of the points and signals, and supplies electricity at 120 to 150 volts; the third battery, divided into four sections of 18 cells each, coupled in parallel, serves for the indicator circuits supplying current at about 30 to 40 volts.

Very simple switches are employed for charging the batteries and for using them in rotation for the operation and for the indicator circuits.

The N. S. R. have found that the consumption of energy measured at the supply circuit (before the accumulators), for operating and for the indicators of thirteen points and one signal at Maarn, is about 0·2 to 0·25 kilowatt-hour per motor per day, of which, the indicator circuit at 30 to 40 volts absorbs about 90 per cent.

The published figure for this consumption amounts at Schwerte for 127 levers and at Düsseldorf for 107 levers to 0·12 kilowatt-hour per lever.

d) Signal operated by carbonic acid.

The N.S.R. has fitted a distant signal on a swing-bridge consisting of a semaphore operated by compressed carbonic acid, of which the mechanism was supplied by Messrs. Siemens & Halske. This signal is at the same time the distant signal of a block signal situated near the bridge-keeper's cabin. The signal arm can

occupy three positions : 1°, horizontal position, showing danger, when the swing-bridge is open; 2°, a position inclined at 45° downwards, requiring slacking if the bridge is closed, and if the block signal is at danger; 3°, a position inclined at 45° upwards, giving " line clear " if the bridge is closed and if the block section is clear.

The signal arm is operated by a lever which can occupy three positions; it is fitted in a lever frame fixed on the side of the canal opposite to that on which the signal is placed. The operating lever is connected to two current switches. It cannot be moved from the danger position to the position for slacking unless the bridge is closed, and cannot be moved from this position or from the danger position to the " line clear " position unless the bridge is closed and when the lever operating the block signal is at " line clear ".

The operating current and the indicator current are supplied by a battery of six accumulators of 10 ampere-hours each, charged by 16 Meidinger cells, while an underground cable containing seven wires connects the appliances to the signal.

The carbonic acid is stored in liquid form in a reservoir at the foot of the semaphore, containing 20 kilograms (44 lb.) of acid at a pressure of 40 to 50 atmospheres; a reducing valve reduces the pressure to 2·5 atmospheres before the gas is admitted to one of the two operating appliances.

The operating appliances consist of two cylinders, each with a piston and each fitted with two valves which are operated by electro-magnets. The valves admit carbonic acid to either side of the piston. The arm is connected by a vertical rod to the centre of a movable rocking-lever. The ends of this rocking-lever are connected by rods and levers to the operating appliances.

The combination of these rocking-levers, rods, and levers is such that the displacement of one of these operating appliances from its normal position moves the signal from the danger position to that for slacking (*caution*), while the operation of the other appliance sets the signal to " line clear ". The throwing back of one of these appliances always sets the signal to danger.

To set the signal to slacking (*caution*) or to " line clear ", carbonic acid is admitted on the upper side of the corresponding piston. The admission valve is opened by sending a current round the electromagnet by pulling a lever (switch) placed in the cabin.

When the piston has reached its lowest position, the mechanism moves the contacts; the current ceases to flow round the electromagnet operating the valve, and magnetises another electro-magnet the armature of which is connected to a stop which interlocks the corresponding bar in the position it occupies at the end of its travel; the valves which have been moved put each end of the cylinder in communication with the atmosphere; the supply of carbonic acid is shut off.

On throwing over the lever, the current in the electro-magnet of the stop is cut off, and the arm falls by its own weight to danger. In case of failure, if it did not

fall in a short period of time, a mechanism which travels a certain distance in a given time, would open an electric circuit passing through the electro-magnet of the stop valve; this valve would open and carbonic acid would be admitted to the under side of the piston.

Under normal conditions, therefore, there is no consumption of gas when setting the signal arm to danger. The carbonic acid reservoir is placed on a balanced plate; when the weight of carbonic acid has diminished below a certain quantity an alarm rings in the cabin. Indicators in the signal cabin show the position occupied by the signal arm.

This apparatus has been at work for three years; its cost, including the signal, the electric cables and operating-lever amounted to 3,600 francs (£144). The carbonic acid reservoir is replaced at intervals of three weeks; the signal is operated about 50 times per day : the derangements which we have had show that such apparatus requires some care in maintenance.

e) Comparison of expenses with hand-levers and with power distribution.

It is interesting to compare the first cost, the cost of operating, and the cost of superintending the installation for the different appliances.

For large installations with hand levers (cabins containing 30 to 70 levers, interlocked with each other by electric-slots or station block-apparatus), one finds that the cost of the central apparatus in the cabins, including the slot-gear and all electric apparatus (alarms, telephones, etc.), varies from 400 to 1,000 francs (£16 to £40) per lever. The lower cost relates to apparatus which has a large number of operating-levers and a small number of route-levers and electric slot-appliances. The higher cost relates to complex apparatus.

A mean cost of 800 francs (£32) is found for 500 levers. Taking count of the fact that with a single lever one often operates two sets of points or two signals, and that 1,000 levers are connected to about 1,300 points and signals, the cost of the central apparatus, per set of points or per signal, becomes reduced to 620 francs (£24.16*s*.)

The cost of installation of the operating apparatus for the points, including some bars, some bolts and some ground signals at points, amounts to 550 francs (£22) per lever, or to 350 francs (£14) per set of points.

In the case of signals, an average of 450 francs (£18) must be reckoned per signal; this average covers the simple disks and also the level crossings with signals which frequently require to be fitted.

The wire transmissions, which are laid at large stations in sheet iron culverts, are found to cost 500 francs (£20) per lever, and 350 francs (£14) per set of points or per signal. The sum of these figures shows that for a complete installation

1,800 francs (£72) per lever, or 1,370 francs (£54.16*s.*) per set of points or per signal, must be allowed.

In installations of normal size on the N. S. R., 1,300 track appliances can be subdivided into 835 sets of point apparatus and 465 signal appliances; it is necessary, therefore, in preparing a preliminary estimate of the cost of a signalling system to allow 2,150 francs (£86) for each set of points. These prices do not include the cost of the cabins; this must be reckoned at from 150 to 400 francs (£6 to £16) per lever according to the type of foundation, the architectural work, etc.

The electro-pneumatic installation at Haarlem cost for 30 sets of points and signals, 84,000 francs (£3,360), or 2,800 francs (£112) per set of points or per signal. The cost of the installation of the motor-compressor, the accumulator, etc., amounting to 20,000 francs (£800) is not included in this sum.

The estimate for a similar installation at Amsterdam for 120 sets of points and signals amounts to 208,000 francs (£8,320), that is to say, to 1,720 francs (£68.16*s.*) per set of points or per signal, exclusive of motive power, accumulators for the indicators and the cabin building. It is to be noted that in the installation under consideration, the H. R. uses a number of small shunting signals, costing only 50 francs (£2) each, which reduces the total by 50 francs (£2) per set of points or per signal.

The price of 1,700 to 1,800 francs (£68 to £72) per set of points or per signal includes 460 francs (£18.8*s.*) for the central apparatus in the cabin and the electric appliances, 410 francs (£16.8*s.*) for electric cables and conduits, 900 francs (£36) for the operating gear for a set of points and those of signals and their accessories.

The compressing plant and its accessories, including the accumulators, cost 20,000 francs (£800) at Haarlem and will cost 33,500 francs (£1,340) at Amsterdam.

For the electrically-operated appliances at Rosendaal and at Maarn, we have found that 2,200 francs (£88) per set of points or per signal must be reckoned.

The central apparatus in the cabin costs about 400 to 500 francs (£16 to £20) per set of points or per signal.

The operating gear for a set of points consists of the point operating gear and a locking device which permits running through trailing when wrongly set; including the expenditure on installing, these have cost, on the N. S. R., 1,100 francs (£44).

The present price quoted by Messrs. Siemens & Halske of 685 francs (£27.8*s.*) (exclusive of 50 francs [£2] for fitting expenses, adjustments and making connections to the electric cables) per set of point-operating gear and of 806·25 francs (£32.5*s.*) (exclusive of 55 francs [£2.4*s.*] for fitting expenses) per signal-operating gear. These prices include free delivery in Holland, but do not include the supply or fitting of detectors to the point-tongues, the foundation frames, or the rodding connecting

the point-tongues with the operating rack, nor do they include the cost of designing the installation for a large station (1).

At Rosendaal and Maarn, the electric cables cost about 500 francs (£20) per set of points or per signal.

The cost of the power supply installations varies greatly according to whether the batteries can be charged direct, or whether special charging plant must be provided. In the small installations at Maarn and Rosendaal the cost was only about 7,500 francs (£300).

It follows from the above details, that in the case of large installations operated by manual labour alone from 1,100 to 1,600 francs (£44 to £64) per set of points or per signal must be allowed; in the case of the electro-pneumatic installations of the firm of Stahmer, 1,700 to 2,800 francs (£68 to £112) per set of points or per signal and 20,000 to 33,000 francs (£800 to £1,320) for the power station; in the case of the entirely electric system of the firm of Siemens & Halske from 1,500 to 3,000 francs (£60 to £120) per set of points or per signal and from 7,500 to 20,000 francs (£300 to £800) for the power station.

SECTION *B*.

Arrangements adopted to ensure that the position of point-tongues taken facing or trailing cannot be altered prematurely or before the train has completely cleared.

The search for an *efficient* arrangement for preventing premature shifting of the points forms one of the most difficult problems to be solved for ensuring safety in railway working.

A mechanical solution becomes more and more difficult in its application because the distance between the axles of carriages is being continually increased; a lock-

(1) The cost of a point-operating gear can be detailed approximately as follows:

1° Apparatus for operating points, capable of being run through trailing, contained in a cast-iron casing, delivered free in Holland	685·00	francs	(£27. 8*s*.).
2° Laying down, adjustment and connections to the cable	50·00	—	(£2).
3° Foundation frame	32·50	—	(£1. 6*s*.).
4° Rodding connecting the point-tongues to the operating-rack	23·75	—	(19*s*.).
5° Detectors for the position of points-tongues	78·75	—	(£3. 3*s*.).
6° Fitting items 3 to 5	31·25	—	(£1. 5*s*.).
7° Cost of preparing designs for a complete scheme for a large station	18·75	—	(15*s*.).
Total	920·00	francs	(£36.16*s*.).

ing-bar or a treadle, formerly of sufficient length, is now too short to prevent the untimely operation of a lever.

Moreover, the points in large stations are more and more entangled, and the appliances necessary to protect against false settings of a set of points then require to be arranged in the crossings or in the preceding set of points.

In the application of the solution of the problem by employing electricity, based on the use of insulated lengths of rail, a new source of trouble is introduced and only the first difficulty is removed; the second remains unaffected.

In the case of a large scissors-crossing at a station with a number of slip-points succeeding each other and extending over from four to eight tracks, it is almost impossible to find a mechanical arrangement which will be efficient and will not get out of order in a short time.

The application of an insulated rail to each of the slip-points on a large scissors-crossing is difficult; it is generally only fitted at the ends of the route taken by trains passing from one track to another.

But if this is done, shunting operations are hindered when they are performed according to signals, or else untimely shifting of the points during shunting of trains is not prevented in the case when signals are being used. Such may occur the more often since the operations have to be performed more quickly when shunting trains than is the case with the ordinary service. Many of the derailments which take place during shunting operations, and of which the causes are not ascertained at the enquiry, may be attributed to untimely shifting of the points which can very easily occur owing to the closeness together of the levers which operate the points.

It should, moreover, be noted that in cases where shunting operations are performed without signals, derailing occurs through throwing over points, not fitted with a treadle (locking-bar) either mechanically or electrically operated, to rectify a wrong setting while the train is approaching.

The mechanical appliances for locking the points (while occupied by vehicles) by means of a bar arranged in advance of the point-tongues, and of a length equal to the maximum distance between the centres of consecutive wheels, may be divided into two categories : 1° those which are operated by the train wheels (treadles); 2° those which are operated by a rocking-lever either connected to the point-operating gear, or which are operated separately.

We can state, without hesitation, that appliances of the first category, constructed to suit different methods of application, have not given satisfactory results.

Their great length involves a very rigid form of construction in order that the depression caused by the first wheel may be transmitted as far as to the point-tongue.

This heavy form of construction requires a rather strong spring to lift the appliance; it follows that the shocks to which the apparatus is subjected by each train are so violent that they speedily cause wear in the appliance and necessitate its renewal after a few month's work. These appliances are damaged when the points are

run through trailing while wrongly set, unless apparatus of complex construction is inserted for this purpose in the transmission rodding.

Appliances of the second category are in use extensively on the railways of the Netherlands.

The N. S. R. has for many years employed treadles, connected to the shunting appliances, of a length of 7 metres (23 feet), and with five points of attachment spaced 1·20 metres (3 ft. 11 $^1/_4$ in.) apart at the ends and 2 metres (6 ft. 6 $^3/_4$ in.) at the centre, and having one end overhanging to the extent of 0·60 metre (1 ft. 11 $^5/_8$ in.) (appendix VIII).

To ensure that it is in proper working order, the treadle is tested every second month by pulling it over against a stop which is fixed to the rails and takes the place of the train wheels.

It is impossible to fix the treadles on the inside of the track at slip-points because of the check-rails which are placed in advance. In such cases, outside treadles are fitted, as shown in figures 16 and 17, which require no explanation.

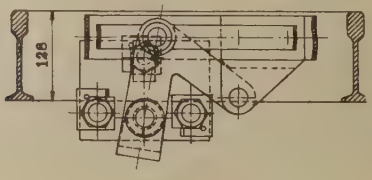

Fig. 16.

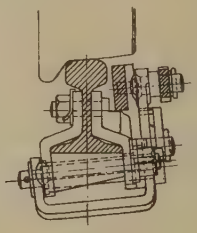

Fig. 17.

The treadles referred to in appendix VIII have the disadvantage that the points of attachment must correspond to the spacing of the sleepers. It is often difficult to find a suitable place for these attachements between the sleepers.

In 1908 we fitted treadles, on the outside of the track, 11 metres (36 feet) in length, the points of attachment of which were carried on a supplementary rail or channel-iron carried on the sleepers.

These treadles and their attachements, carried on the auxiliary rails, are not subjected to the forces which act on the track rails.

The H. R. has treadles in use which differ but little from those employed on the N. S. R. (see figs. 18 and 19).

The N. S. R. considers that a treadle 7 metres (23 feet) in length is sufficient even for a longer distance between consecutive wheel centres. It is satisfied that after one moving wheel has left the treadle, its upward moment is directly prevented by the approach of the succeeding wheel,

Recently some treadles 11 metres (36 feet) long, fitted outside the track on an

auxiliary channel iron have been put to work. It is possible to avoid this extra length by adopting an improvment in the construction of the points recently devised by Mr. Boland, engineer to the N. S. R.

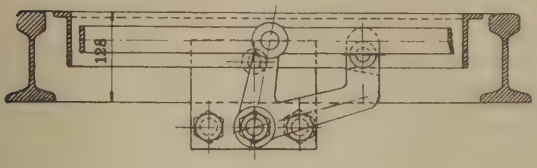

Fig. 18.

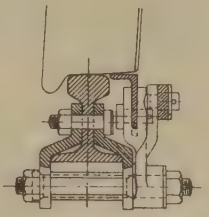

Fig. 19.

This invention consists in the use of " lifting " point-tongues instead of " sliding " point-tongues. As shown in figures 20 and 21, the end of the point-tongues is fitted with a shaft which moves in a hole in a small vertical lever, having its fulcrum on another shaft fixed to the point-chair.

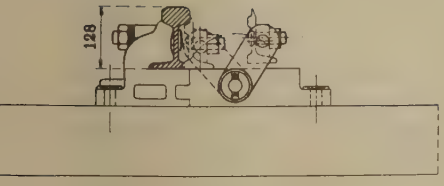

Fig. 20.

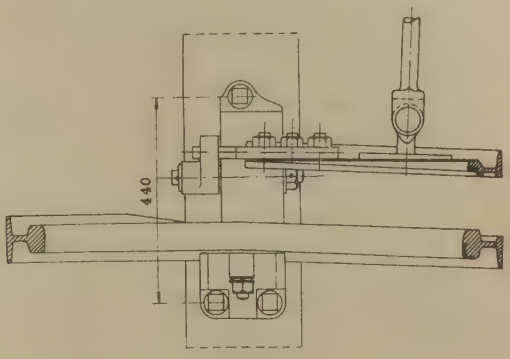

Fig. 21.

In its normal position the point-tongue rests on the chair; on throwing it over it lifts above the rail because its point is forced te follow the curve described by the extremity of the short lever. During the latter portion of its travel, the point falls again because the lever passes its vertical position. On again setting the point to normal position, it falls against the rail, so that it is certain to occupy its proper position.

Thus one portion of the point-tongue serves as a treadle, because it is impossible to lift it when it is occupied by a wheel.

The portion of the point-tongue near the heel does not act as a treadle, because it

is possible to depress it a few millimetres by the application of a force equal to that produced by the operating mechanism.

By combining this construction of point-tongues with treadles 7 metres (23 feet) in length, the arrangement for preventing premature shifting of the points is lengthened so as to attain 11 metres (36 feet) in length, which appears sufficient at the present time.

At the commencement of this report, we drew attention to the fact that it is difficult to connect treadles to all the points which form the large scissors-crossing for a number of tracks at the entrance to a large station.

Such a system already comprises a very complex system of mechanical construction. The numerous fastenings and the large quantity of moving pieces subjected to successive blows by the trains, require careful maintenance. This maintenance should not be hindered by the presence of parts of numerous apparatus which are not an absolute necessity.

But if treadles are abolished, it is necessary to have recourse to other arrangements for preventing premature shifting of the points, particularly under passenger trains. The most simple arrangement consists in the interlocking of the point-levers in the cabins in such manner that it is impossible to operate them before the train, for which the signals have been set to " line clear ", has reached a certain place.

When the home signal at the cabin A cannot be pulled off without the intervention of the block-apparatus in the cabin B, the following combination is all that is necessary; after the signal has been again set to danger, the points on the route from cabin A remain locked until cabin B has unlocked them, and B does not do this until the moment when the train passes his cabin.

The N. S. R. utilises this combination in many of its stations. The disadvantages attendant are known : in the case of derailment, it is impossible to assign the blame, because it cannot be proved that B has not unlocked A too early; and in the case when B is late, the shunting operations are hindered. For the departure signals this combination cannot generally be used, but it can be seen that the consequences of an accident to a train leaving the station are less serious than to one entering the station, because the question of speed is of less importance.

It is in those stations in which the service is crowded, that the disadvantages of the system are the greatest. For this reason the N. S. R. has fitted in the past few years, on some portions of its system, an arrangement for unlocking those points which form the route by making the train itself act on an electric rail-contact which may or may not be combined with an insulated length of rail (appendix IX).

CONCLUSIONS.

LITTERA A. — *Improved centralized installations for operating switches and signals. The use of water, of compressed air, of electricity, for working the transmissions Electric interlocking. Route levers.*

The safety appliances in the Netherlands resemble in many respects the types of appliances in use in Germany and in Austria. The semaphore with arms takes the place of the disk signal used in those countries in the case of the distant signal.

For operating the points and the signals, double steel wire transmission has been exclusively in use for the last 30 years. These transmissions, which extend up to 550 metres (600 yards) for points, and up to 1,100 metres (1,200 yards) for signals, are only fitted with compensating gear under exceptional circumstances.

The distant signals are constructed in such manner as to fall to danger in case of breakage of the wire. No arrangements have been adopted for locking the points in case of breakage of the wire.

The outermost points, worked at a distance of more than 250 metres (273 yards) are bolted. One of the two companies, the company for working the Netherlands State Railways, has extended the use of bolt-locks to the greater number of the important point-tongues, where these are taken facing by express trains. Many points are fitted with operating gear permitting them to be run through trailing when wrongly set.

The safety appliances, with the exception of the interlocking of the points, consist in general in that the signals cannot be set to "line clear" except with the mutual consent of two cabins. The use of signals with superposed arms showing the route is only adopted to a limited extent on the lines of the company for working the Netherlands State Railways. The drivers find a point signal slightly raised at the outer points of small stations for giving the direction at places where trains pass without stopping.

The Holland Railway Company, by adopting candelabra semaphores in several stations, has attempted to show the drivers the route which they are to take.

The company for working the Netherlands State Railways has adopted the use of the same signals for the trains and for shunting operations inside the stations, whereas the signals of the Holland Railway Company apply only to trains in transit.

The company for working the Netherlands State Railways has adopted a system of line normally blocked on its main line, whereas the Holland Railway Company has adopted the block-system with line normally clear.

* * *

Centralised appliances for working points and signals depending on the use of

compressed air or electricity as motive power, can be applied with success to large stations. These appliances have the advantage that they require no physical effort from the staff.

The degree of safety obtained with these appliances is greater than that obtained by hand-lever gear, because it is possible to have a permanent indication in the cabin of the position of the point-tongues and of the signals.

The Stahmer electro-pneumatic appliances have not shown the disadvantages which have often been attributed to them. It must be stated that the maintenance of tightness of the piping, and that condensation from moist air have not given rise to trouble.

The electro-pneumatic appliances can be applied without the addition of special mechanism to point-tongues consisting of flexible rail, in order to permit of the points being run through trailing when wrongly set.

The cost of electro-pneumatic installations and of entirely electrical installations is, exclusive of the cost of supply of energy, higher than that of the double-wire mechanical installations, although there are cases in which the costs differ little.

The cost of the electro-pneumatic installations is, for a small number of levers, much greater than that of the entirely electric installations. For installations of small size and of great extent it is necessary to work out the cost for each particular case.

The cost can be diminished by constructing the operating mechanism for the points and signals in large quantities of the same dimensions, by means of special machinery, and in a factory equipped for this purpose, as in the case of bicycles and sewing machines. It would be well to unite the appliances for operating and those for locking the point-tongues in a single appliance which could be fixed without difficulty to all points.

It is possible that in operating signals, the solenoid has some advantages. It has to be noted that even though the efficiency of the solenoid is less than that of the rotating motor, the question of efficiency is of no great importance, because the energy required for operating is only a small portion of the total energy required including that necessary for the indicator.

Littera B. — *Arrangements adopted to prevent switches taken from the facing or the trailing side from changing their position before the whole train has passed.*

It is possible to construct mechanical treadles (locking-bars) for separate points operated by the double-wire, which, when well maintained, can give satisfaction for a distance of 7 metres (23 feet) between consecutive wheel centres. In combining these treadles with points fitted with point-tongues which lift in their to and fro movement, the distance between consecutive wheel centres may attain 11 metres (36 feet).

If the distances at which the appliances are operated are not great, mechanical treadles 11 metres (36 feet) in length, can be operated with the points. These treadles have disadvantages in case the points are taken trailing when wrongly set.

For the numerous arrangements of points which are found in a large station, the use of separate treadles is almost impossible. It is necessary to have recourse to the bolting of routes. This bolting is unlocked after the passage of the train, either by the following cabin, or by a block-apparatus at the cabin itself, which can only be unblocked on condition that the train has passed a certain place.

These combinations usually apply only to the regular trains; the shifting of a set of points under a train during shunting is not prevented.

It appears to be of importance that efficient forms of construction should be found, which may be applied to points whatever may be their situation, and which may apply to vehicles having successive axles at a great distance from each other, both for trains and for shunting operations and without causing delay where the traffic is congested.

APPENDIX I.

Description of central appliances by Messrs. Siemens & Halske for operating points and signals.

Figure 22 shows a front view and figure 23 a section of an apparatus fitted with an interlocking box containing 26 bars corresponding to 26 route-levers. Figures 24 and 25 show appliances having a greater number of bars; the supplementary boxes are fitted above the former (fig. 24), or more recently behind the appliances (fig. 25).

The two vertical supports for the apparatus are connected by two cross-frames of channel iron, R_1 and R_2, and by the interlocking box. These cross-frames carry the pedestals I, which carry the shafts for the chain pulleys and the levers H with their spring handles *h*.

The box A contains the electric slot-gears and the magnet is fitted above the interlocking box.

The interlocking between the levers is effected by a system of horizontal shafts fitted with tappets in the plane of the pulleys on the levers,and of horizontal bars, fitted with stop-pins, running in the direction of the length of the apparatus.

Vertical rods form the connection between the interlocking box and the levers. For each lever one rod corresponds to the normal position and another rod to the thrown-over position of the lever. The interlocking box is shown in figure 28, in which the combinations can be easily followed.

The rods 18 between the interlocking box and the hand-levers are guided through apertures formed in the frame of the pedestals, and are connected to the shafts by the intervention of the short levers 7.

The shafts are fitted with springs 17 or handles *k*. The spring-operated shafts correspond generally to the levers actuating the points; the spring 17 tends to lift the rod 18 and to make it leave the notch cut in the rim of the pulley.

The shafts with handles correspond to the routes; normally they are locked by means of a continuation of the handle formed as a cam *kk* (figs. 26 and 27) which engages with a notch cut in a fixed circular plate embracing the shaft and secured to the sheet iron cover.

The operate the shaft, one must press on the free end of the handle so as to disengage the cam from the notch, to the bottom of which it is pressed by a spring; at the end of its travel, the cam engages in the notch corresponding to the thrown-over position.

The shafts with handles serve to displace the interlocking bars. These bars are guided above the shafts between separating teeth in the form of a rack, spaced about

---

Note. — At Arnhem station, there is an apparatus with five frames, measuring each 2,300 millimetres (7 ft. 6 $^9/_{16}$ in.), carrying 27 point-levers, (nearly all for double slip-points), 31 signal-levers, 90 route-levers, and 58 electric slot-gears.

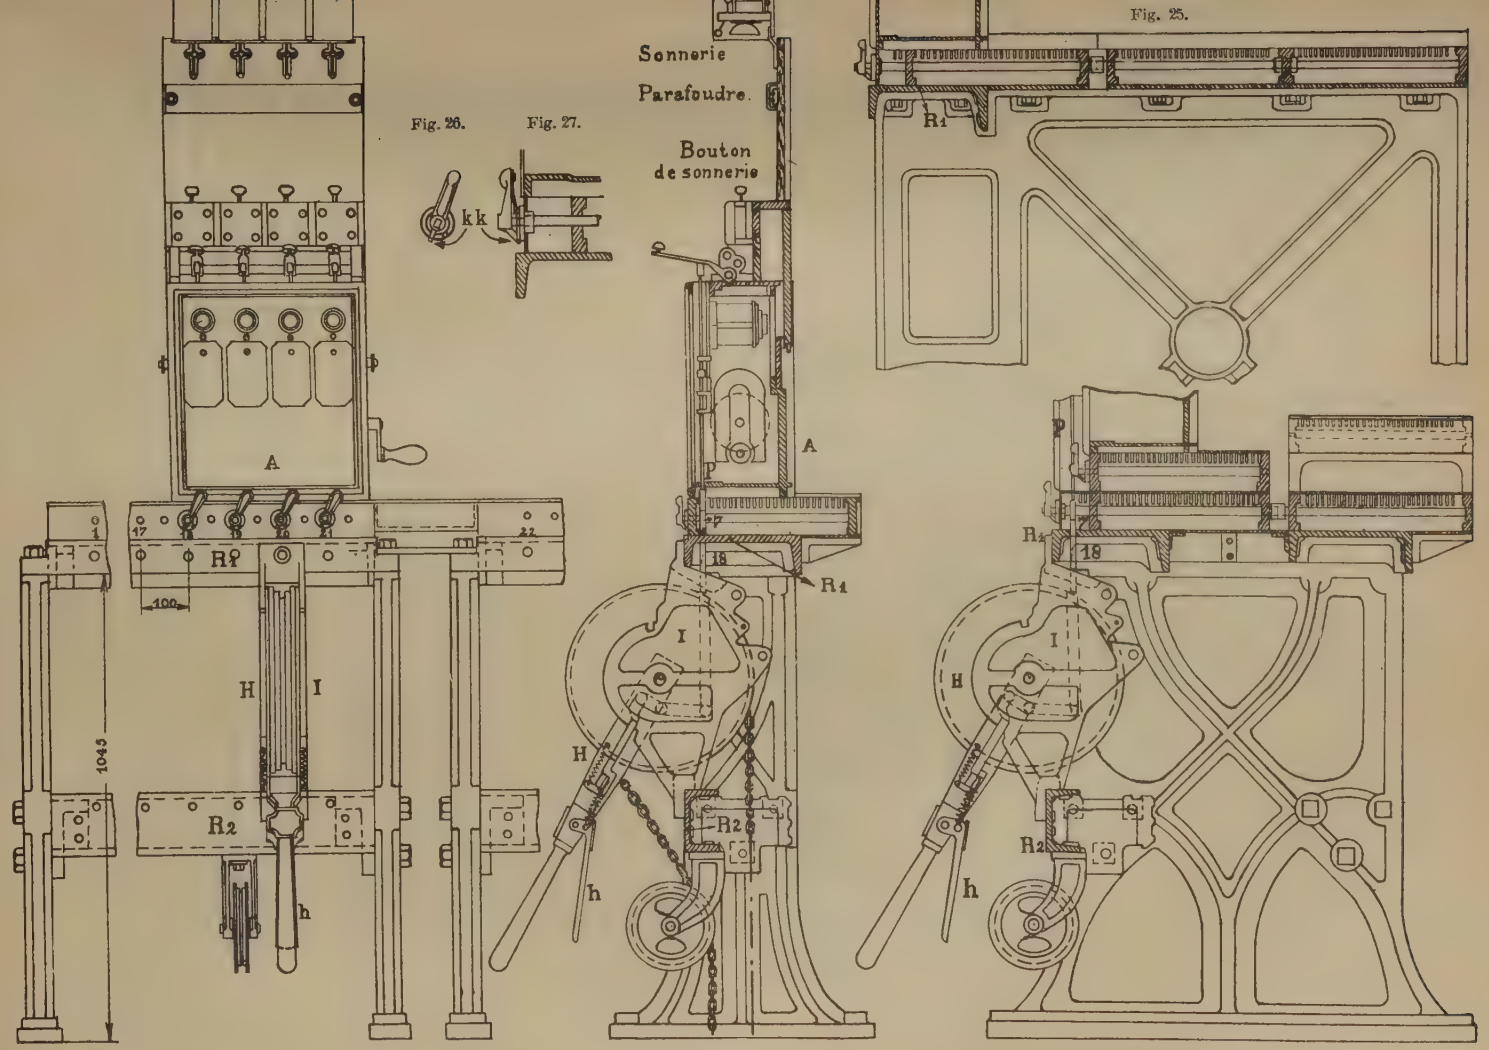

Fig. 22.

Fig. 27.

Figs. 22 to 27.

Explanation of French terms : Sonnerie = Alarm bell. — Parafoudre = Lightning arrester. — Bouton de sonnerie = Push button of alarm.

1 metre (3 ft. 3 3/8 in.). These bars lock or free the shafts corresponding to the levers interlocked.

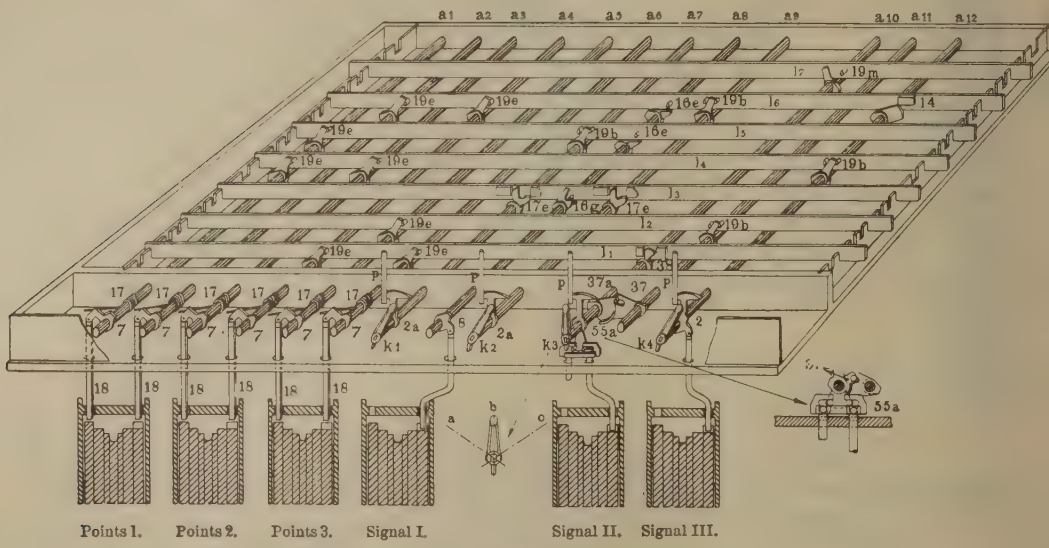

Fig. 28.

The shafts should be fitted with special cams when they are to be interlocked by the rods *p* of the electric slot-gear.

We will now examine how the interlocking is effected. The ordinary interlocking $\frac{-\text{III}}{-1\ -2}$ (the signal III is interlocked with points 1 and 2 in their thrown-over position) is effected by the route-lever *k*4, fitted on the shaft *a*12. The displacement of the handle *k*4 acts through the tappet 19*b* placed between two stop-pins, giving a to and fro movement to the bar *l*4. This bar interlocks the points 1 and 2 in their thrown-over position by means of the tappets 19*e*. The handle *k*4 frees the signal III, the interlocking with the block apparatus is obtained by the cam 2, carried on the same shaft *a*12.

Conditional interlocking such as $\frac{-\text{I}}{-1 \text{ or } +1+2}$ (signal I must be freed under two sets of circumstances; the one corresponds to the thrown-over position of points No. 1, and the other to the normal positions of the points Nos. 1 and 2) can be effected by means of two route-levers *k*1 and *k*2. In operating the handle *k*1 and the shaft *a*7, the bar l_3 is displaced by the tappet 17*e*, and the bar l_5 by the tappet 19*b*. By displacing the bar l_3 and the tappet 16*g*, the shaft *a*8 is operated, and the signal I is freed; by the displacement of the bar l_5, the shaft *a*1 is rotated and the points No. 1 are interlocked in the thrown-over position.

On operating the handle $k2$ and the shaft $a9$, the tappet $17c$ displaces the same bar 1_5, whereas the bar 1_6 is displaced by the tappet $19b$ and the points Nos. 1 and 2 are interlocked in their normal position.

After operating the signal 1, the tappets $16c$ interlock the bars 1_5 or 1_6. On displacing the bar 1_6 the tappet 14 and the shaft $a12$ are interlocked by a small plate fixed to the bar. Conversely on turning the shaft $a12$, the bar 1_6 is locked.

To economise space, handles have been made of the form known as double direction handles k^3 which can occupy three positions, a, b, c, the position b being the normal position. On operating the handle from the position b to the position a, the bar 1_4 is displaced by means of the shaft $a10$, from right to left; points Nos 2 and 3 are interlocked in the normal position and the shaft $a11$ cannot be moved.

On throwing over the handle from the position b to the position c, by special mechanism $37a$ 37, the adjacent shaft $a11$ and its corresponding bar 1_2 are displaced in the same direction from right to left, while bar 1_4 remains fixed.

By a special tappet $55a$, the rod l is lifted from the pulley of signal 11 on operating the handle from its position b to its position a, and also on operating it from the position b to the position c. The operation of the handle from right to left can only be performed when the rod P of the electric block-gear is raised.

It will be readily seen that the double-direction route-levers form an important improvement in the parts necessary for obtaining conditional interlocking.

The bars are 7 millimetres ($^9/_{32}$ inch) thick, 30 millimetres (1 $^3/_{16}$ inch) deep, and are placed 7 millimetres ($^9/_{32}$ inch) apart; all the tappets are 6 millimetres ($^1/_4$ inch) thick; their bosses which carry the screw for attaching them to the shafts, are placed below the bars. All the details of the interlocking box are of small size to which there is no objection, because it is impossible to exert a great force on the mechanism the handles being only 100 millimetres (3 $^{15}/_{16}$ inches) in length.

The distance between the electric slot gears and the levers is 100 millimetres (3 $^{15}/_{16}$ inches). The shafts are placed from 45 to 55 millimetres (1 $^3/_4$ to 2 $^3/_{16}$ inches) from each other.

The details of the point levers (figs. 29, 30 and 31) are constructed in such manner that the parts which serve for attachment to the wire by means of a chain can be disconnected from the lever when, owing to the points being taken trailing when wrongly set, a certain amount of force is applied to the wire. In the normal position, the pulley and the lever are maintained connected by means of a system of spring ratchets connected to the lever and embracing a projection on the pulley. When the force applied to the wire exceeds the tension on the spring, the pulley turns, whereas the lever remains in its place.

After the points have been run through trailing, the operation of the signals interlocked with the points, as well as the operation of the point-lever, is rendered impossible until the pulley has been restored to its original position.

If the points are taken trailing while wrongly set and while the interlocked signal is set to "line clear," the parts of the apparatus suffer no damage.

The levers with a spring-latch are constructed in such manner that the interlocking is effected by the raising of the latch before the commencement of the movement. This position does not vary during the movement of operating; the interlocking can only take place when the lever is not at the end of its travel, and when its latch is not dropped into the thrown-over position.

Fig. 30. — Section on CD.

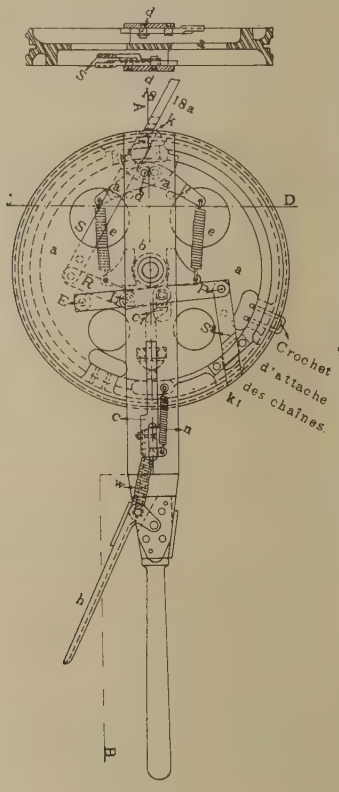

Fig. 29.

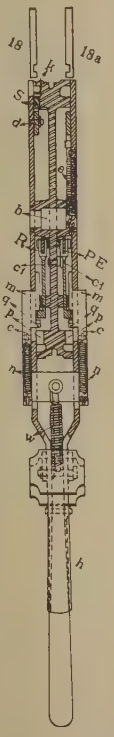

Fig. 31. — Section on AB.

Figs. 29 to 31.

Explanation of French terms : Crochet d'attache des chaines = Hook for fastening the chains.

The pulley turns about the shaft *b*. The lever is built up of two flat bars which turn freely on the boss of the pulley, one on each side; the flat bars are connected outside the pulley by a piece of steel, to which the lever is fixed.

The parts connecting the pulley to the lever consist of two spring-controlled

rocking-levers *a* pivoting on the gudgeon-pin *d* bolted to the flat bars. The rocking-levers engage the extremities of the raised rims with which the pulley is provided under the action of the springs *e* ; on the one side these cover an angle from 0 to 190°, and on the other side from 170 to 360°. The pulley and the lever are thus locked together so long as the forces which tend to disengage them do not stretch the springs to such an extent that the ratchets slip internally along the raised rims.

In the case of the points being taken trailing when wrongly set, the tension of the springs must be overcome. This tension must not be too great, otherwise the intermediate parts will be forced out of place or broken. It must be sufficient to ensure connection between the pulley and the lever if, for any reason whatever, at the end of the travel, the force acting on the wire should be increased to some extent.

To avoid the disadvantage which would arise when the tension on the springs is exceeded during the operation of setting the points, a movable piece forming one with the lever is interposed between the lever and the pulley. This interposition takes place when, by means of the handle *h* the latches *c* guided by the flat bars, are displaced against the action of the springs *n*. The latches *c* carry projections *m* and *q*.

When the latches are displaced, the projections *m* are disengaged from the notches formed in the segments on the pedestal, whereas the projections *q* engage in the notches *p* which are formed in the rims of the pulley. The projections *m*, when raised, slide over the edges of the pedestal, during the operation of the lever, in such manner as not to interfere with the connection between the lever and the pulley.

The interlocking rods 18 and 18*a* (fig. 31) are normally placed above the edges of the pulley. One of these rods 18, can be engaged with the notch *k* in the right hand edge, in the normal position of the pulley; the other 18*a* in a notch *k'* in the left edge, in its thrown-over position.

In figure 31, the point-tongues can be interlocked in the normal position. By pressing on the handle *h* to operate the lever, one acts through the pieces *c*, on two other pieces c^1. One of these pieces c^1 is connected to a lever PE turning about a shaft E, on one side of the pulley, while the other is connected to the rocking-lever R, turning about the shaft L on the opposite side.

By means of the rocking-lever R the piece S^1, guided by the edge of the pulley, is acted on, and can engage with the notch *k* below the rod 18. The movement of the lever PE is transmitted to a piece S^2, which in the thrown-over position of the lever comes below the rod 18*a* in a direction parallel to that of the piece S^1 in its normal position.

If the interlocking allows it, all the parts can be displaced, and the lever can be thrown over.

If the interlocking does not allow it, and if the rod 18 is engaged in the notch in the edge of the pulley, the operation of the lever is rendered impossible.

In this case the rocking-lever R and the piece *c* are locked; it is impossible to subject the mechanism to a force greater than that which corresponds to the stretching of the spring W inserted between the handle and the latches *c*.

After an angular movement of about 150°, the lever and the pulley come into the

thrown-over position. The latches *c*, raised during the operation, can act under the force exerted by the spring *n* owing to the fact that there is a second notch in the segment of the circle carried on the pedestal. They can move with the pieces S^1 and S^2 in the direction of the pivot; the interlocking rod 18*a* can be displaced, and the points can be interlocked in the thrown-over position.

The points can be taken trailing, when free or when interlocked with the signal. In the first case the pulley revolves, the ratchet levers shift, the pieces *c* and c^1 are disengaged, and the ratchets *a* slide along the rims of the pulley; the signalman is informed by seeing a red indicator disk and by the noise made that the points have been run through trailing.

After the points have been taken trailing, it is impossible to set the corresponding signal to "line clear", because the rods 18 and 18*a*, resting on the edges of the pulley, prevent this.

When the points are interlocked with the signal, and when they have been run through trailing, the outer edge of the pulley slides in a groove formed for this object in the rod 18, which is engaged in the notch.

In both cases the operating lever remains locked, because the projection *q* of the latches *c* is displaced in relation to its notch.

By re-setting the pulley and the points to a position corresponding to that of the lever (this being effected by means of a special lever), the connection between the lever and the pulley is established.

APPENDIX II.

Description of the central apparatus on the « Alkmaarsche Yzergietery » system for operating points and signals.

The levers of the signals and points which are fixed to the grooved pulleys can turn on the shafts A (fig. 32); these carry four levers in a group, are fastened to the cross-frames B, and are spaced 500 millimetres (1 ft. 7 $^{11}/_{16}$ in.) from centre to centre. The cross-frames are secured to each other by the rods D, which run the whole length of the lever frame; distance pieces through which the rods pass ensure the proper spacing of the cross-frames. The back part of the cross-frames is so arranged as to carry the brackets which serve as guides for the locking bars; the upper portion of the cross-frames serves to carry the block-apparatus of the Siemens & Halske pattern.

The travel of each lever is limited at each end by a movable catch *a* which engages in notches cut in the edges of the cast-iron stop plates E. The catch is operated by the catch-handle *b* pivoted to the lever C; in its travel it slides on the edge of the stop plate E which is of circular form. The stop-plates E, placed between the pulleys, are carried at one side on the shafts A and at the other side on angle-irons fitted between the cross-frames.

The levers and pulleys are of simple form, the movement of the catch-handle does not act on the parts which themselves lock or unlock the pulley.

The interlocking system consists of vertical shafts and horizontal bars; the former are fitted with tappets of the form of short levers which act on stop-pins fixed to the bars. The vertical shafts carry small lever arms on their upper ends which serve to operate them, and they carry tappets in the middle of their length which act on the horizontal locking bars. These bars enter the rims of the lever-pulleys and lock them.

The routes are arranged by the plungers F (figs. 33 and 34), the stops *c* and c^1 on which limit the travel by coming in contact with the bar *d*. To unlock a signal, the signal I for example which corresponds to the route set by the plunger F, it is necessary first to push the plunger to the left through a few millimetres against the action of a spring. The horizontal stop *c* can then pass through the hole in the plate G and it becomes possible to move the plunger outwards. This action moves the small lever on the shaft *f*1 and causes it to rotate; the shaft *f*1 carries a fork *g* at the middle of its length and this acts on the stop-pin of a bar *h*.

After this movement, the plunger is locked by moving it to the right when the stop *e* bears on the other side against the plate G.

In figure 34 displacement of the bar *h* is only possible when lever No. 4 is in its normal position and when lever No. 5 is in the thrown-over position. This displacement has the effect of disengaging the spring rod *i*, which is normally locked by

the tappet *k*1. The spring-bolt *i* acts direct on the pulley of the signal I, which is consequently freed.

Conditional interlocking is obtained by inserting a rocking-lever between two plungers; a supplementary plunger is fixed to the centre of this as is shown in figure 34 for the plungers F2 and F3.

The plungers F2 and F3, by means of the small levers *g*2 and *g*3 of the shafts *f*2 and *f*3, operate the locking-bars of the points *h*2 and *h*3 (fig. 33); the supplementary rod F2, 3 rotates the shaft *f*2, 3 the tappet on which disengages pulley No. 3 of signal No II.

The ends of the block apparutus do not act direct on the plungers, they disengage or lock the ratchets *m*, lifted by a spring. The tooth on the ratchet acts on a stop *n* on the plunger.

Many of the appliances are fitted with special interlocking apparatus between the plungers which are carried in a box mounted on brackets at the back of the apparatus. The interlocking arrangements are generally provided for the purpose of disengaging a particular signal by the action of any one of several route-levers. The plungers are in such case lengthened by rods. Stop-pins are bolted to these rods, which slide in openings, either straight or inclined, recessed in thin bars. These bars are displaced by operating the plungers (fig. 34).

The levers and the pulleys shown in figures 32 and 35 cannot be run through trailing when the points are wrongly set; figures 36 and 37 show levers which satisfy this condition. In this case the pulley turns freely on the boss of the hand-lever. A spring-lever I connected to the pulley engages with a stop, the faces of which are slightly inclined where they enter the notch in the lever. In case of running through the points trailing, the tension on the spring is overcome and the pulley turns relatively to the hand-lever. On moving the lever, a stop on the catch-bolt is engaged in a notch in the inner edge of the pulley rim, and thus the engagement between the lever and the pulley is re-established.

This construction does not admit of the points being taken trailing when wrongly set in cases when the points are locked by the movement of a signal-lever.

APPENDIX III.

I. — Description of shunting appliances arranged for taking trailing on the N. S. R.

Figures 38 to 42 show the shunting appliances on the N. S. R. which are arranged for taking trailing.

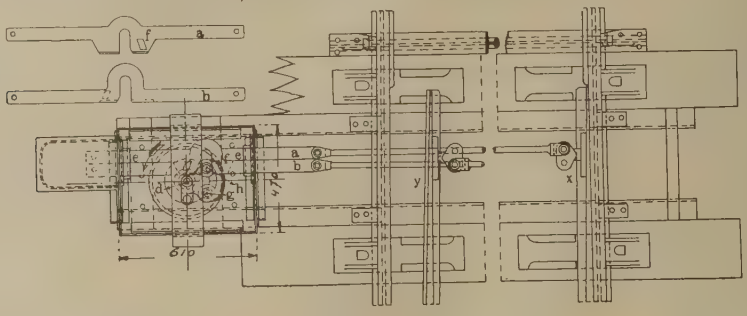

Fig. 38.

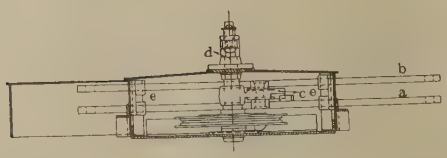

Fig. 39.

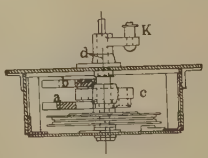

Fig. 40.

Abb. 42.

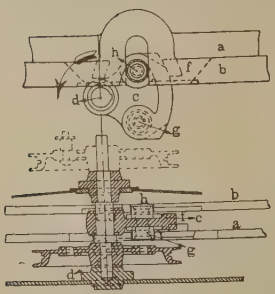

Fig. 41.

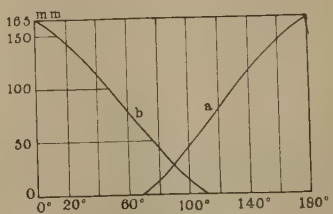

Fig. 43.

They consist of a closed box constructed of plate and angle-irons; a movable shaft *d* passes through the centre and is fitted with a pulley and chain; this is placed at the

bottom of the box where underground transmission is used and above the cover in the case of transmission above the surface.

The shaft carries a cam *c* formed as a quadrant of a circle (figs. 41 and 42) and fitted with two rollers, the one *g* below, and the other *h*, above the cam. The roller *h* engages in a groove in the plunger *b*, whereas the other roller *g* engages, after displacement of the cam, with the groove in the plunger *a*.

The plungers are guided in cast-iron blocks *e*, bolted to the walls of the box. The plunger *a* is connected to the point-tongue x, and the plunger *b* to the point-tongue y.

When the roller *g* has left the groove, the edge of the piece *c* holds the tappet *f* of the plunger *a*, in such manner that the plunger *a* and the crossbar are so held that the point-tongue x remains pressed against the stock-rail. At the same time, the plunger *b* and the corresponding point-tongue are held in place by the roller *h*. When the pulley is turned in the direction of the arrow, the point-tongue is then immediately displaced, and the movement takes place according to the curve *b* shown in figure 43. The point-tongue x remains fixed until the moment when the roller *g* engages with the groove in the plunger *a*. The point-tongue x moves as shown by the curve *a* in figure 43.

When the points are taken trailing, the point-tongue is pressed towards the rail; the plunger *b* acts on the roller *h*, which can turn with the cam *c*, because the direction of the movement of the plunger *b* and of the line *hd* are inclined to each other at an angle of about 45°.

The movement of the cam *c* is transmitted by the pulley shaft and by the wire transmission to the operating-lever.

At a certain point in its travel the roller *g* enters the groove in the plunger *a*, and carries the latter with it; the point-tongue x will be displaced through a sufficient distance at the moment when the flange of the wheel tends to press it away from the stock rail.

The shaft *d* must be fitted with a small lever *k*, acting on the rods of a locking-bar.

The appliance is mounted on two angle-irons fixed to the rails.

As it is absolutely necessary to maintain the distance between the rails constant, a crossbar, fitted with two chairs, is placed in front of the points.

In all those systems which can be taken trailing, the crossbars connecting the point-tongues together must be omitted.

The rodding connecting the operating-gear is attached to special pieces fixed to the point-tonges. Each of these pieces is fitted with two holes with steel bushes so that it is possible to connect the rodding wherever it may be required, and to change the point of attachment in case of wear.

The same appliances are used for operating the point-tongues of slip-points Usually the four point-tongues of a set of double slip-points are combined with the four opposite point-tongues of a following set of double slip-points as shown in figure 44.

Fig. 44.

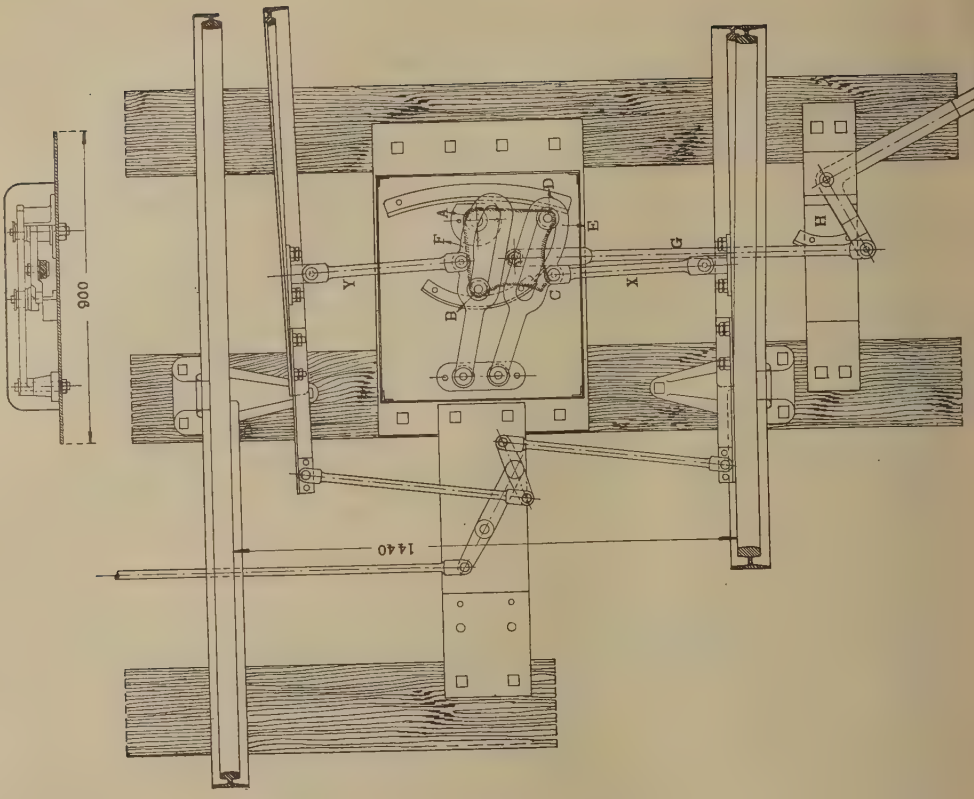

Fig. 47.

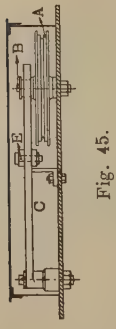

Fig. 45.

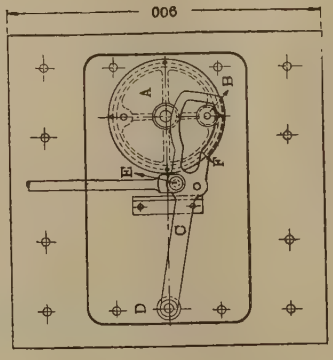

Fig. 46.

II. — Operating gear of points which cannot be taken trailing on the H. R.

The appliances for operating and locking those points which cannot be taken trailing on the H. R. (figs. 45 and 46) are very simple. They consist of a pulley A which is connected to the transmission and carries a roller B almost at its circumference. A lever C, pivoting about a pin D, is formed with an opening of special shape, in which the roller works. The lever is connected to the point-rods at E. When the pulley turns, the roller follows the interior contour of the opening as far as F, before displacing the lever. On reaching F, the roller acts on the lever and causes it to turn till it reaches the point diametrically opposite. When it reaches this point, the lever moves no further, because the roller follows the opposite circular arc, thus in about the first third of the movement, the points are unbolted; in the second third they are shifted, and in the last third they are again bolted.

The mechanism is covered with sheet-iron and fitted direct on the sleepers.

III. — Appliances which can be taken trailing on the H. R.

The appliance arranged for being taken trailing on the H. R. is shown in figures 47 and 48. The mechanism operating the point-tongues consists of a piece of cast-iron of the form ABCD, turning about a pin A and sliding at C along a curved angle-iron. This piece carries two rollers at B and D which, in a displacement through 90°, move the slotted levers E and F and at the same time shift the point-tongues by the action of the rods X and Y.

In the first third of the movement, the lever F and the point-tongue Y are shifted, while lever E and the point-tongue X are unbolted; in the second third of the movement, two point-tongues are thrown over, and in the last third of the movement, the lever F remains in position and the point-tongue Y is locked.

The movement of the piece ABCD, is effected by the rod G which is connected to the jaw of a bell-crank H, one arm of which is connected to the transmission. For this reason, the transmission should be fitted with a return pulley placed beyond the points.

When points fitted with this appliance are taken trailing by a train, the point-tongue corresponding to the rod Y is deflected; it carries with it the piece ABCD, and after moving a certain distance, this piece causes the other point-tongue and the transmission to move with it.

The points are connected to a system of rodding and levers, which operate the ground-signal of the points or the bar of the bolt-lock in such manner that it is necessary that both the point-tongues should be at the end of their travel for the signal to show the proper setting of the points or for the bolt-lock to be shifted.

For operating slip-points the H. R. uses the same appliances as the N. S. R.

APPENDIX IV.

Description of the Marissen compensating gear.

Figures 49 to 51 show the arrangement of the Marissen compensating gear. The working of this appliance is very simple.

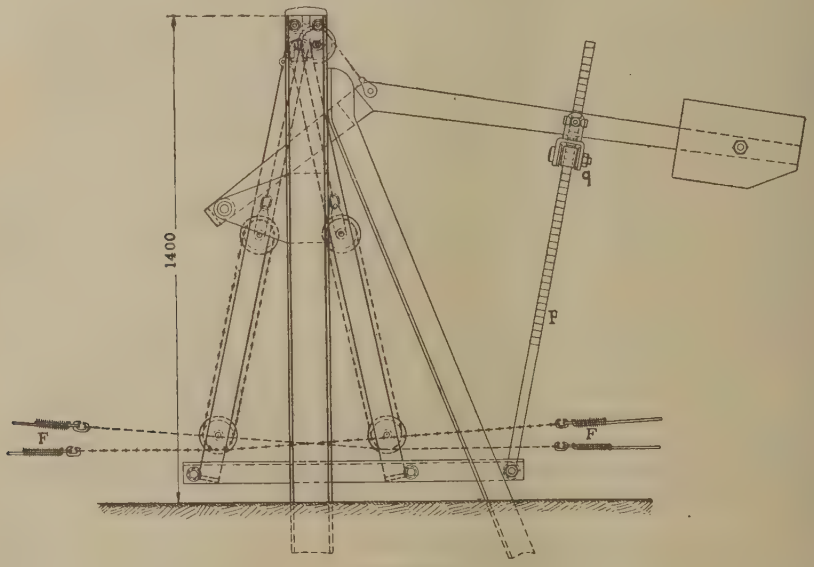

Fig. 49.

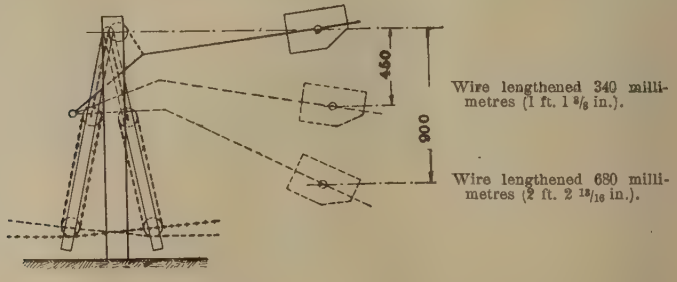

Fig. 50.

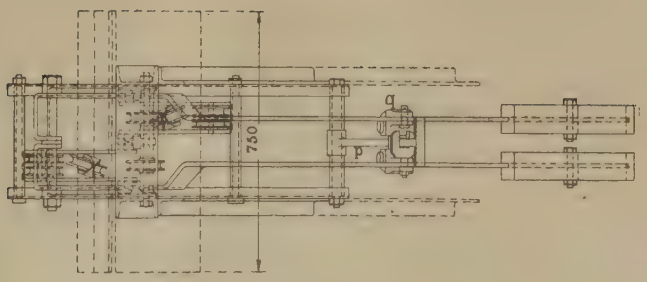

Fig. 51.

When the wire lengthens by expansion due to rise of temperature, the compensating weights fall, and the distance between the pulleys which are guided in the swing-levers increases.

When the wire shortens, the weights are lifted, and the distance between the pulleys is diminished. When operating, the swing-levers swing in opposite directions while the portion of the transmission between the swing-levers keeps the same length and the compensating weights remain in place.

A system of tappets q, connected to the levers of the compensating weights, engages with the teeth of a movable bar p and prevents too much stretching of the wire in the event of any unforeseen load coming on the transmission.

The oscillating movement of the apparatus requires scarcely any force to be supplied by the signalman. In ordinary appliances, where the transmission runs over many pulleys, a considerable force is required in performing the operation of the appliances.

The compensating weights are fitted in such manner as to give the wires a tension of 70 kilograms (154 lb.).

APPENDIX V.

Description of locking bars worked from track circuits.

Figure 52 shows in diagrammatical form an installation of two tracks at a station on a single-track line; it only shows the station block apparatus connected by means of four electric wires to the two cabins I and II placed at the ends of the station. One of the electric slot-gears A, of the Siemens & Halske pattern, relate to the direction P, whereas the other slot-gear B corresponds to the direction Q. In the case of cabin I the train can take either of the two routes on arrival, from P on to track 1 and from P on to track 2, and it can take two routes on departure, the one from 1 to P and the other from 2 to P. One only of these four routes can be used at a time. It is therefore sufficient to have an electric slot-gear in the station, which can be connected alternately to one of the four wires which are connected in the outer cabin to one of the four electric slot-gears. These slot-gears interlock or free the home signals on track 1 or on track 2 or the starting signal on one or other of these two tracks. The route, that is to say, the corresponding electric wire, is chosen by operating one of the plungers *a* and *b* or *c* and *d*, in one direction or the other, and by thus closing, for example by means of the plunger *a*, the contacts 1-2 and 3-4, or the contacts 2-5 and 3-6. The plungers are interlocked with each other, by means of bars, as show in figure 34. The interrelation between the unlocking of the arrival road and the occupation of this road is obtained by track relays placed above the block apparatus; the relay *1* relates to track 1, and relay *2* to track 2.

The relay windings are connected on the one side to a battery and on the other side to the insulated wire 1*r* of the insulated track No. 1, and by the insulated wire 2*r* to the insulated track No. 2.

In operating the electric gear A to unlock the home signal at cabin I, the contact 8-7 is closed so that the pulley P of the battery is connected by means of the insulated wire 3*r* with the non-insulated rails and to earth.

If the track is occupied by a vehicle which forms an electric connection between the two rails forming the track, the battery circuit is closed by the 4 ohm resistance of the relay electro-magnet. The relay armature is attracted and opens the contact 11-12 for track 1 and the contact 9-10 for track 2.

These contacts being interrupted, it is impossible to set the corresponding signals to "line clear". When these contacts are made, if the rod *p* of the slot-gear A is pressed down, and if the plunger *a* is displaced in the direction of the arrow, a current can be sent by operating the magneto of the block-apparatus I. This alternating current from the brush *i* can pass through the contact 9-10, the contact 4-3, and thence to contact 13.

The current passes thence through the electro-magnet of the slot-gear A to the contacf 2-1 of the plunger, and passes through insulated wire 2 to cabin I.

After the electric slot-gear A has been blocked, the plunger *a* is locked in the

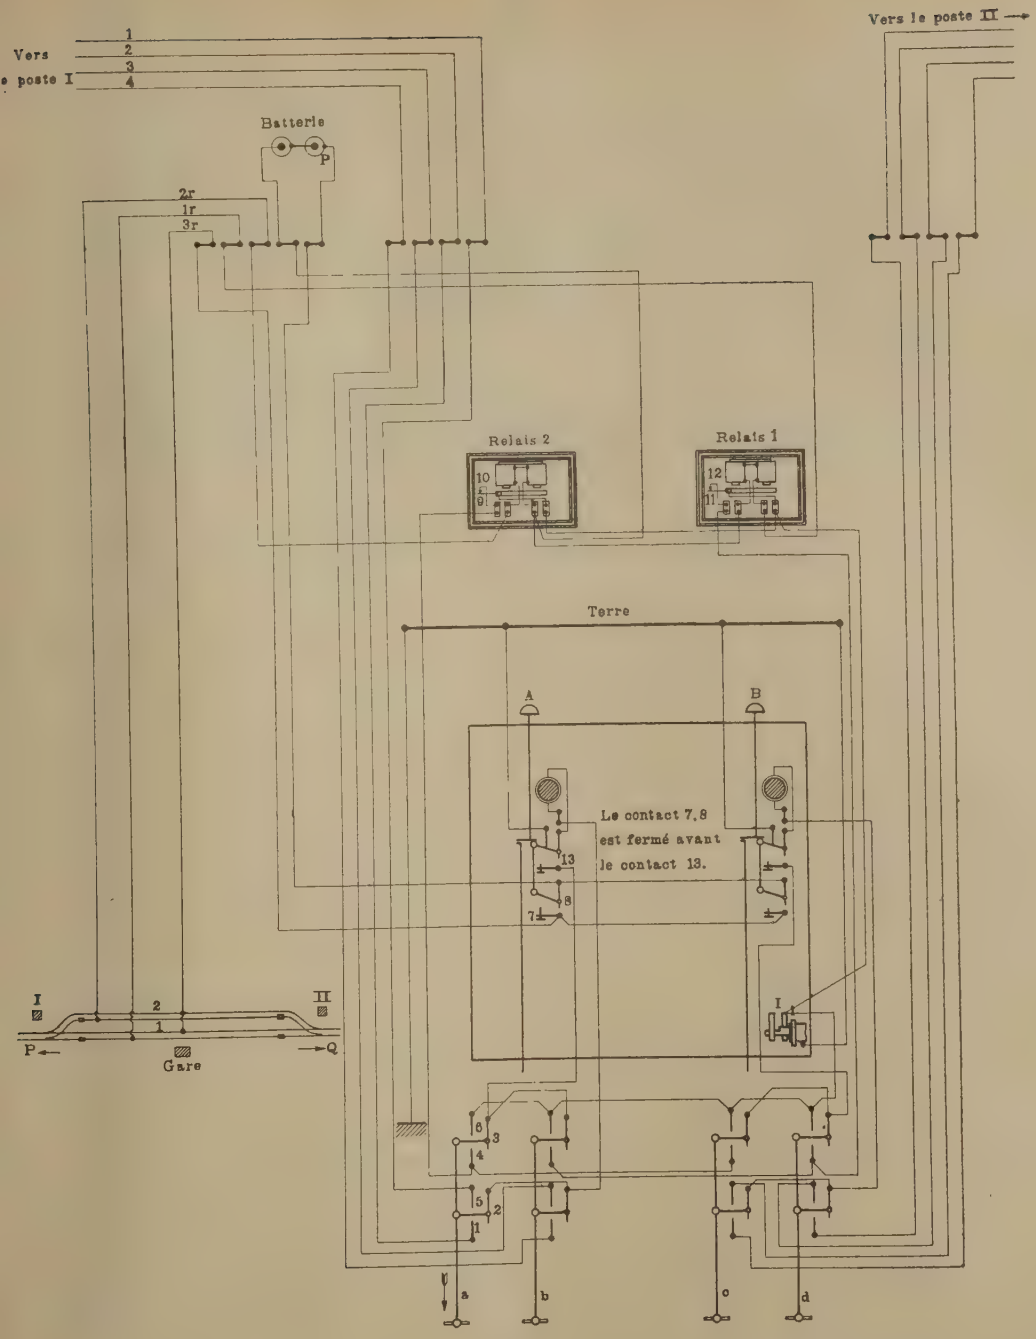

Fig. 52.

Explanation of French terms : Gare = Station. — Batterie = Battery. — Relais = Relay. — Terre = Earth.
Le contact 7.8 est fermé avant le contact 13 = The contact 7.8 is closed before the contact 13. — Vers le poste I = To cabin I.

thrown-over position; it is maintained in this position until the unlocking current is sent from cabin I. The circuit of this current is independent of contact 9-10. Contact 7-8 is only closed when the push-button of the slot-gear is pressed home: a vehicle occupying the insulated track section consequently has no influence on the relay. It follows that after performing the operation for admitting a vehicle to the track, the armature of the relay cannot remain held against the core of the electro-magnet owing to bad insulation of the track.

The insulated rail section only extends over that portion of the track, on which passenger trains are usually stopped. Its length is only from 200 to 250 metres (219 to 273 yards); the insulation is maintained between 20 and 200 ohms; this length appears to us very short.

Formerly the H. R. employed 6 Meidinger cells as the battery, arranged in groups, 2 in series and 3 in parallel; in practice the contacts 7-8 are inserted and two Leclanché cells appear to be sufficient.

APPENDIX VI.

Description of appliances for operating points and signals by means of compressed air at Haarlem station (H. R.).

The installation (fig. 13) comprises a cabin with electro-pneumatic operating appliances for 25 sets of points, 2 stop-tappets, 1 point-lock and 4 signals.

Compressed air is used as the motive power, and the action of this force is regulated from the apparatus in the cabin, which is so arranged that the points and signals are moved when electric current is transmitted.

A compressed air main pipe, which does not run into the cabin, is laid along the track and is fitted with branches leading to each set of points and each signal.

The operating gear for each set of points comprises a cylinder fitted with a piston operated by compressed air.

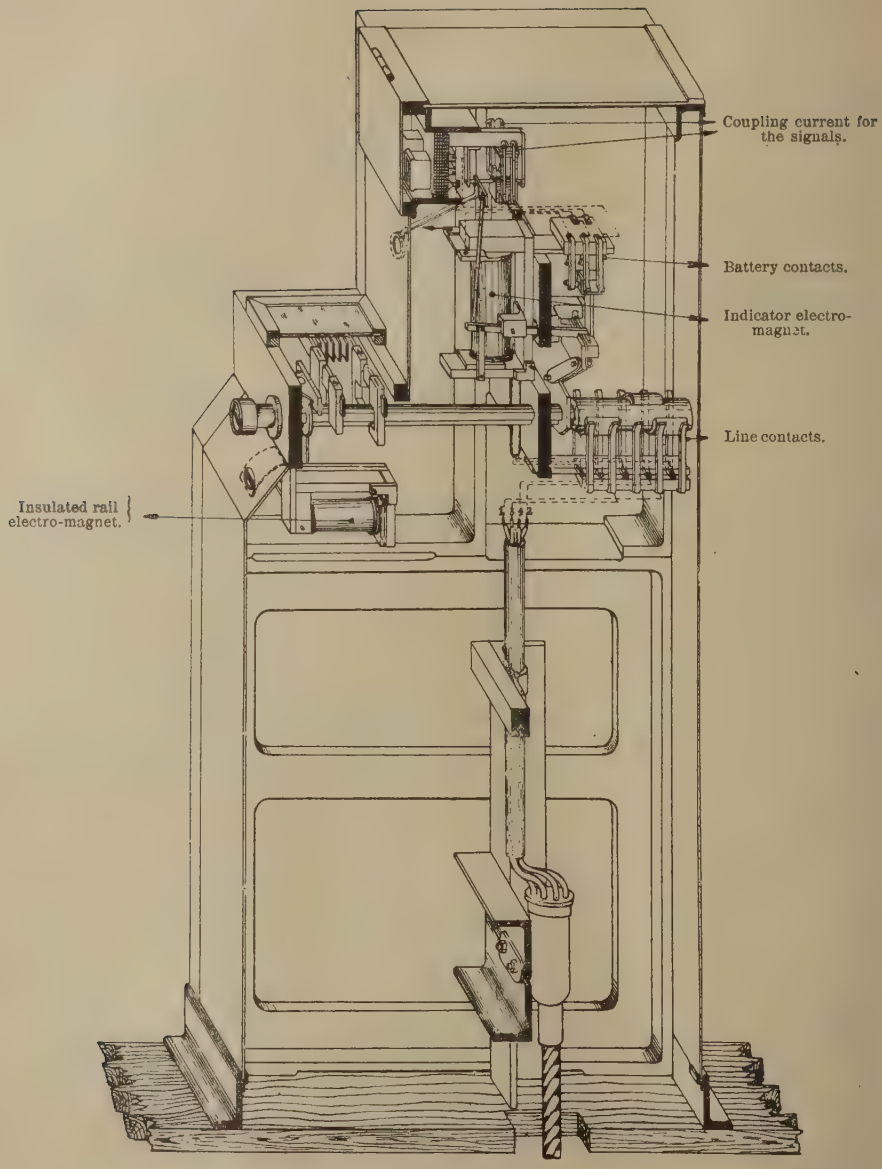
The piston is connected — by means of a rocking-lever for reducing its stroke — with the rodding connected to the point-tongues. Compressed air is admitted to one end or the other according to the position of a piston valve. When compressed air is admitted to one end of the cylinder, the air which is contained in the other end, can escape. The slide-valve is also moved by compressed air, and the admission of the air to both ends of the cylinder in which the piston-valve works is regulated by poppet-valves which are connected to the armatures of two electro-magnets.

The operating-gear for each signal consists of a cylinder in which moves a piston connected to the signal arm. The apparatus is so arranged that the electric current passing round the electro-magnet opens an admission valve and closes the exhaust valve; this allows compressed air to enter the cylinder and thus operates the signal arm. When the circuit is broken, the small poppet-valves are placed in the reversed position and the air is allowed to escape. The counter-balance weight then drives back the piston and with it the signal to the normal position.

The construction of the central apparatus in the cabin is very nearly the same as in the last pattern made by Messrs. Siemens & Halske shown in figure 53. We say "very nearly", because the appliances installed at Haarlem as well as those at Rosendaal, are of an earlier type, in which the controlling electro-magnets, the shafts carrying the contacts of the batteries, and the shafts carrying the contacts for coupling the signals, are installed below instead of above the hand-lever shafts.

We will first examine the diagrammatic arrangement of a set of apparatus for operating one set of gear (fig. 54) which differ only in detail from those in use for the routes and for the signals. The ordinary levers of the lever frames are replaced by shafts of special section (fig. 1).

These shafts are rotated by means of a push-key, either through 90° from the normal position to the thrown-over position in the case of points and of ordinary signals, and from 90° to the right to 90° to the left for two routes and the corresponding signal.



Coupling current for the signals.
Battery contacts.
Indicator electro-magnet.
Line contacts.
Insulated rail electro-magnet.

Fig. 53.

Fig. 54a.

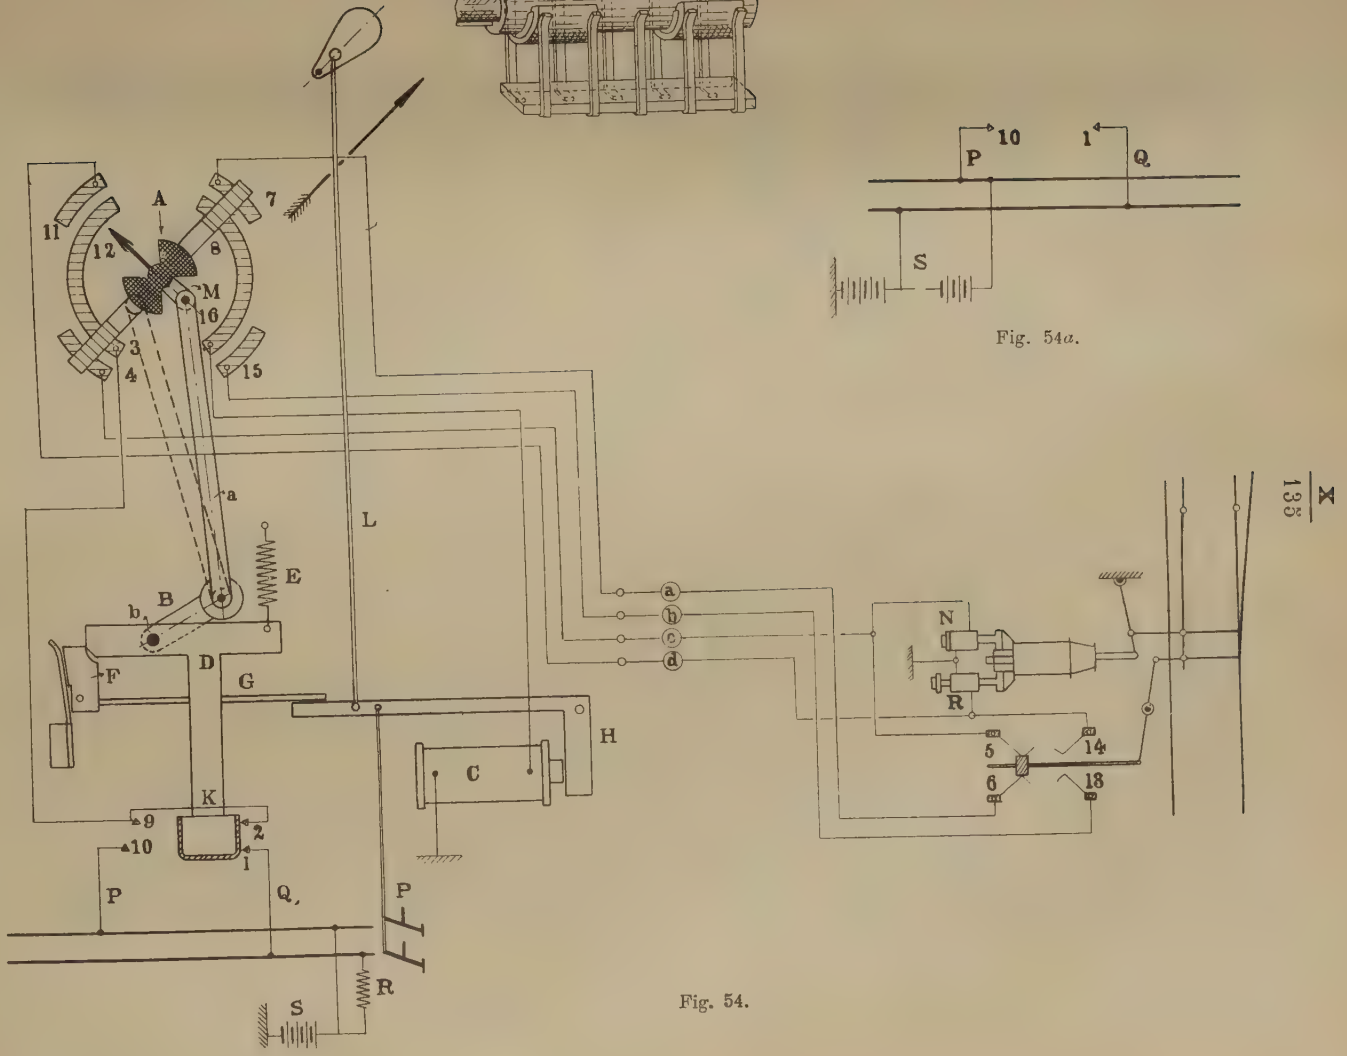


Fig. 54.

The shafts A (fig. 54) are fitted in the front part with tappets, which interlock with the locking bars, as shown in figure 1, and the back part with bronze segments which can make contact between copper fingers (the contacts are constructed like the brushes of a cylindrical commutator, as shown in the sketch placed alongside the figure). The contacts are arranged for : 1° directing the operating currents, and 2° conducting the indicator currents which circulate after the operation has been completed.

While the button is turned, a crank arm M, fixed to the shaft A is lowered, and then raised by the intervention of the rod *a* and the lever B turning about the fixed shaft *b*.

While the lever B is lowered, the piece D, turning about the same shaft *b*, and acted upon by the spiral spring E is displaced. The mechanical armature F of the piece D is disengaged, the stem G withdraws the armature H from the indicator electro-magnet C. The piece D is fitted with a prolongation K, which in one position connects the contacts 1 and 2, and in the other the contacts 9 and 10. The rod L of the drop-disk in the indicator apparatus is attached to the armature G of the electro-magnet C.

When the lever B is in its lowest position, the different parts occupy the positions shown in figure 55; the position they take after the push-key and its shaft have been pushed home is shown in figure 56.

After the points have been operated, the indicator current at a tension of 100 volts excites the electro-magnet C; the armature H is attracted; the mechanical armature F is lifted; the piece D resumes its normal position under the action of the spring F (fig. 54), while the crank-arm M and the rod *a* remain in the position shown by the dotted line in figure 54, and that shown in figure 56, and the voltage of the current flowing to the electric-magnet C is reduced to 20 volts.

Let us now examine the diagram of the circuits.

Normally the current supplied by accumulators S and through the resistance R, passes through the contacts 1, 2, 3, 4, and the wire *c* to the electro-magnet N of the point-tongue. A shunt circuit passes through the contacts 5-6 of a bar connected to the point-tongues by a wire *a* to the contacts 7 and 8 of the operating gear, and thence by electro-magnet of the indicator C to earth. The electro-magnet of the point-tongue N holds a valve in such position that compressed air is admitted to a piston valve, the ports in which correspond to the normal position of the motor piston operating the point-tongue. Contacts 5 and 6 give the indicator the position corresponding to that of the point-tongue when home; when the contact is broken, the indicator current passing through the electro-magnet C is cut off, and this is made apparent in the cabin apparatus.

On displacing the push-key and the shaft A, the contacts 1-2, 3-4 and 7-8 are opened, while the contacts 9-10, 11-12 and 15-16 are closed. The current ceases to flow through the wire *c*, while the current from the accumulators S flows through the wire *d*, without going through the resistance. The electro-magnet N is no longer excited, whereas the admission valve, acted upon by a spring, moves in such manner that compressed air is no longer admitted to the piston-valve cylinder.

At the same time, the electro-magnet R of the point-operating gear is excited by the

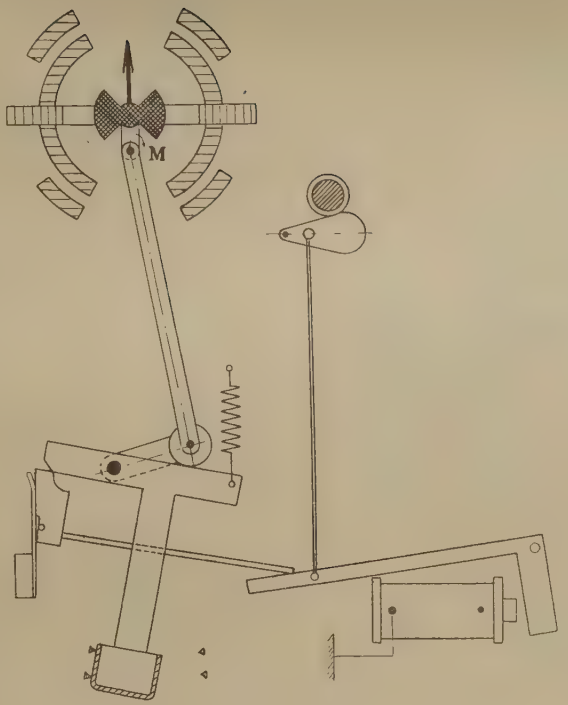

Fig. 55.

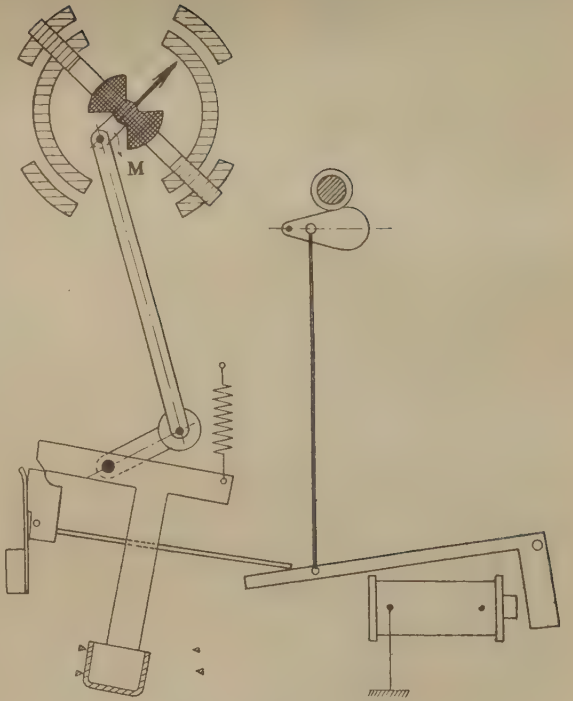

Fig. 56.

current flowing in the wire *d* and goes to earth at the apparatus. The electro-magnet operates the valves, the piston-valve is displaced until its ports correspond to the thrown-over position of the piston actuating the point-tongue.

At the end of the travel of the point-tongue the contacts 13 and 14 are closed; a shunt circuit is formed through these contacts, the wire *b*, the contacts 15 and 16, the electro-magnet C, and the indicator apparatus again indicates that the point-tongue is in its home position against the stock-rail.

The armature of the electro-magnet of the indicator actuates the contact rod P. These contacts can be inserted in a circuit (known as the coupling-circuit) which excites a coupling electro-magnet, the armature of which must be attracted before it is possible to press the push-key of the corresponding signal.

APPENDIX VII.

Description of the apparatus mentioned in appendix VI (for operating appliances by compressed air), for electric operation of points and signals at Rosendaal station.

The apparatus described in appendix VI serving for electro-pneumatic operation at Haarlem station is of the same construction as that employed for the electric operation at Rosendaal.

Figure 54, together with figures 54*a* and 57, 58 and 59, shows the installation diagrammatically.

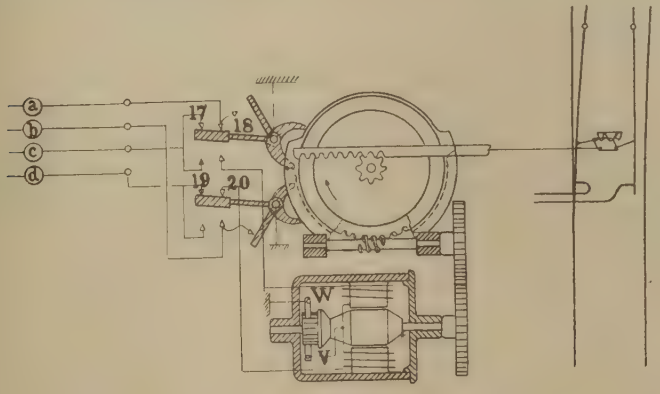

Fig. 57.

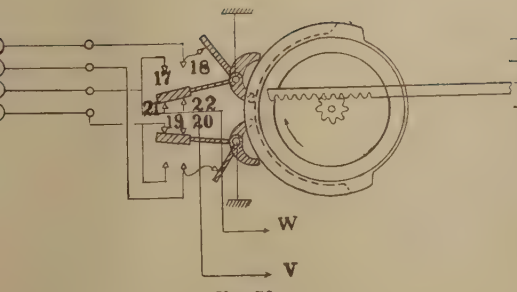

Fig. 58.

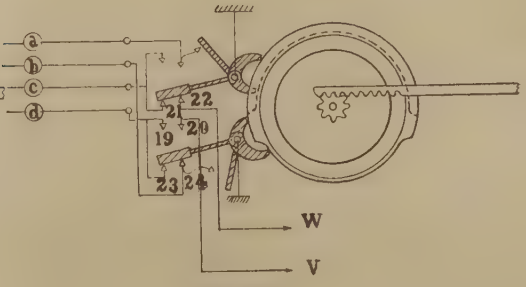

Fig. 59.

Under normal conditions the indicator current, supplied by some accumulator batteries S at 20 volts (fig. 54*a*), passes through the wire Q (fig. 54) the contacts 1-2, 3-4 to the wire *c* (figs. 54 and 57). The indicator contact 17-18 (fig. 57) of the operating-gear of the points being closed, the current passes through the wire *a* to the contact 7-8 and thence through the indicator electro-magnet C to earth. When the contact 17-18 on the operating-gear is open, the indicator current ceases to flow, and this is revealed in the operating-gear by the indicator electro-magnet.

On moving the push-key and shaft A, the contacts 1-2, 3-4 and 7-8 are opened, while the contacts 9-10, 11-12 and 15-16 are closed.

The current in the wire *b* ceases to flow, whereas the current from all the accumulators, passing through the wire P flows through 9-10 and 11-12 to the wire *d*.

This current passes through the 19-20 and the winding V of the electro-magnets, and through the armature of the motor to earth. When the motor has made a few turns (fig. 58) the contact 17-18 are broken, and the line *a* put to earth. The wire *c* is connected to earth by the contacts 21-22 and the winding W of the motor. This arrangement serves to put the motor in communication with the two wires *c* and *d*, so that the points are forced to follow all the movements forward or backward of the operating push-key.

At the end of its travel, the different contact-pieces are displaced and appear as shown in figure 59. The contact 19-20 is broken, whereas the contact 23-24 is made. The current coming from the line *d* is no longer supplied to the motor, but flows through the wire *b*, the contacts 15-16 and the indicator electro-magnet C.

The armature H is attracted, the piece K comes from the position shown in figure 56 to the position shown in figure 54; the contact 9-10 is broken, and the contact 1-2 is made, so that the working current which was flowing through the indicator electro-magnet is replaced by the indicator current at 20 volts.

APPENDIX VIII.

Description of mechanical treadles in use on the N. S. R.

The treadle attachments are constructed as shown in figures 60 and 61 when placed inside the track, and as shown in figures 16 and 17 when placed outside the track.

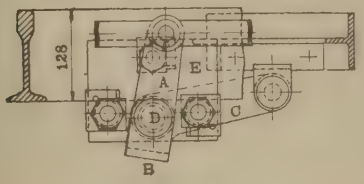

Fig. 60.

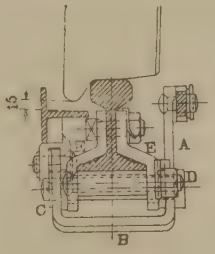

Fig. 61.

The attachment shown in figures 60 and 61 consist of a double lever ABC of curved form, formed of a flat bar and arranged partly below the rail and partly alongside the rail. This lever turns about a pin D, fixed to the plate E secured to the rail. The portions A of the levers are connected by a flat iron bar, which forms the transmission through all the attaching levers of the treadle to the operating gear. The portions C carry the T-bar forming the treadle by means of forked pieces.

The portion C of the lever is in a position considerably removed from the vertical line when the treadle is in its highest position. The wheel can touch the treadle when raised, without injuring it; the wheel then causes the treadle to be depressed.

This action is transmitted to the operating-gear so that the point-tongue is held tightly against the rail. The weight of the treadles tends also to hold the point-tongues against the rails; those points which are fitted with these treadles therefore can scarcely ever remain half-set.

The lifting of the treadle in relation to the movement of the point-tongue is shown diagrammatically in figure 62.

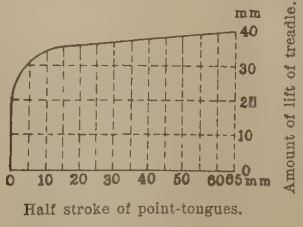

Fig. 62.

The total elevation of the treadle is 40 millimetres (1 $^{9}/_{16}$ inches); at the moment when the bolted point-tongue is going to be displaced the treadle is raised 20 millimetres ($^{15}/_{16}$ inch); when the space between the rail and the point-tongue has opened to 10 millimetres ($^{3}/_{8}$ inch), the elevation of the treadle is increased to 35 millimetres (1 $^{3}/_{8}$ inches).

As shown in figure 61, the flange of the wheel thus prevents rising of the treadle after it has lifted 15 millimetres ($^{5}/_{8}$ inch) but as it is only after 20 millimetres ($^{13}/_{16}$ inch) of movement that the points begin to move, the danger of premature operation of the point-tongues is prevented.

In the preceding, it is assumed that the travel communicated to the levers ABC is equal to that of the operating-gear of the points themselves, even in the case of the furthest apparatus; but according to our own experience this degree of perfection cannot be relied on.

A wheel placed at that extremity of the treadle furthest from the point-tongue, prevents its being operated, if the sinking, the stretching, and the shifting, under heavy loads, are not too great in relation to the travel of the operating mechanism. If this is not the case, the operation of the treadle while under the wheel of a vehicle becomes possible. When the travel and consequently the lift is great, the operation of the treadle is more effective; a large lift demands considerable force for operating, consequently we are compelled to limit ourselves to the lift of 40 millimetres (1 $^{9}/_{16}$ inches).

APPENDIX IX.

Description of an electric treadle apparatus at the termination of a route for trains departing from a passenger station.

The lever L of the block signal covering the succeeding section, which is locked by the electric slot-gear A (fig. 63) in relation with the succeeding cabin, is further interlocked with a supplementary electric slot-gear B. This latter slot-gear works in relation with a slot-gear C, locking the route. The interlocking of the slot-gear C with the route is such that it can be blocked independently of the locking of the points by the intervention of the route-lever *c*, but once this lever has been thrown over, the points, after the signal has been returned to danger, remain locked until the slot-gear C is unblocked.

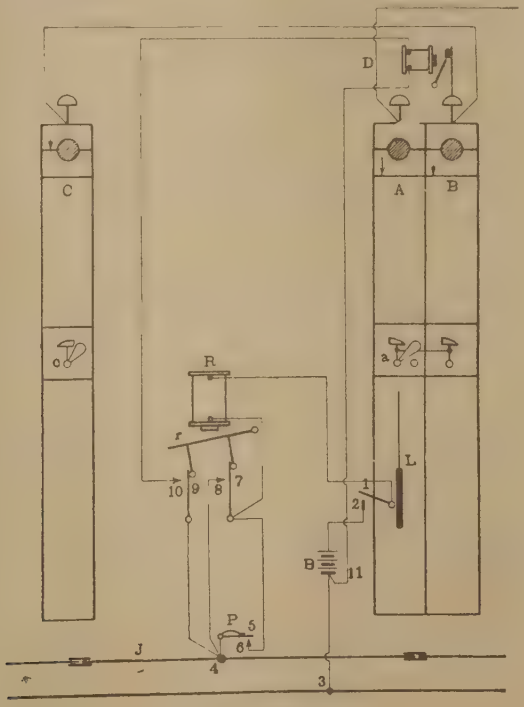

Fig. 63.

When the slot-gears A and B are unblocked, it becomes possible to set starting signal to "line clear" by throwing over the level L.

The train having departed, it is impossible to block the electric slot-gear B and to unlock the electric slot-apparatus C before the train has run over the insulated rail length and the signal has been again set to danger. Figure 63 shows the installation diagrammatically.

The electro-magnet D, of which the armature acts on the rod of the slot- apparatus B, is placed in a box above the slot-gear B; a relay R and a battery B are placed in the cabin.

The contact 1-2 is fitted to the pedestal of the signal-lever; the contact is closed when the signal stands at "line clear."

If a wheel of a train is on the insulated rail J and acts on the treadle P, the circuit — B, 3, axle, 4, 5, 6, relay, 1, 2, battery — of the current from the battery B is closed, the armature *r* is attracted, and the contacts 7-8 and 9-10 are closed.

After the wheel has passed over the treadle, the current in the relay continues to flow, because the circuit 3, axle, 4, 8, 7, R, 1, 2, has not been interrupted.

The electro-magnet D is not excited in either of these two cases because the circuit 11, electro-magnet D, 10, 9, 4, axle, 3, 11, is closed and D is short-circuited.

When the axle has left the insulated rail length, the current passes through the relay and the electro-magnet D; this current is interrupted at 1-2 when the signal is again set to danger.

The armature of the electro-magnet D is retained by a spring-catch after it has been attracted.

The electric slot-gear can be blocked while the armature is attracted. This operation having been performed it becomes impossible to block it again, because the catch is displaced.

The insulation of the rail is effected by means of oiled horn-beam fish-plates. These fish-plates are the same as those used by the Belgian State Railways and described in the number of the *Bulletin of the Railway Congress* for August 1904. Trials made with American fish-plates, in which the insulation is obtained by means of insulating material placed between the rail and the steel fish-plates, have given bad results.

The insulation obtained on a length of 24 metres (26 yards) (2 rails connected by fish-plates and copper connecting wires) has never fallen below 20 ohms. The relays have a resistance of 6·5 ohms. It is important that the connecting wires which connect the rails to the cabins should be of low resistance. To obtain perfect working of the relays, it is necessary that these conductors should be of copper wire from 3 to 4 millimetres (0·118 to 0·157 inch) in diameter.

REPORT N° 4

(Great Britain and colonies, Belgium, France and Italy)

By L. WEISSENBRUCH,

ENGINEER IN CHIEF,

DIRECTOR OF THE SAFETY APPLIANCES DEPARTMENT OF THE BELGIAN STATE RAILWAYS,

and J. VERDEYEN,

ENGINEER,

ASSISTANT TO THE DIRECTOR OF THE SAFETY APPLIANCES DEPARTMENT OF THE BELGIAN STATE RAILWAYS.

SECTION *A*.

Improved central installations for the operation of points and signals.

I. — INTRODUCTORY NOTE.

It has been the custom to give the greatest freedom to the Reporters in interpreting the questions asked by the permanent Committee of the Congress.

In our opinion, section A of question X relates exclusively to central installations arranged for operating points and signals by means of power obtained from a power supply system. In fact, a serious beginning in the direction of progress and in the realization of improvements, worthy of the name, in the signalling arrangements of large stations only commences as soon as the signalman no longer has to use his own muscular effort; when, in English phraseology, " power signalling " has been adopted; or when, if the term be preferred, " fluid-operated cabins " have been installed.

This is also the interpretation adopted

*

by our colleague, Mr. E. C. Carter, who has drawn up the report on question X for the United States (1).

On the other hand, Dr. Ulbricht, the reporter for central, northern and eastern Europe, has entered into a preliminary investigation in which he has covered all the improvements made in existing installations of mechanical signalling (2).

Our colleague, Mr. L. H. N. Dufour, whose field only covered the Netherlands, in which country only limited trials have been made of fluid-operated cabins, was led to draw up a very complete and interesting monograph on the mechanical installations for operating points and signals in Holland (3).

We have in the first instance, in deference to our distinguished colleague, Dr. Ulbricht, drafted our detailed list of questions on that adopted by him. Unfortunately the countries over which our investigations extend, comprise a territory which is much less homogeneous than that which was reserved for Dr. Ulbricht to report upon.

The railways of Italy, France and England follow widely different methods in the arrangement of their mechanical signalling appliances. The replies received from them, — generally very brief, — reached us extremely late in most instances. To comment upon them properly, it would have been necessary to have obtained additional detailed particulars, the time for obtaining which was not available.

The methods adopted in various countries for mechanically operating points at a distance, were, moreover, set forth as far back as 1889 at the Paris Session by Mr. Sabouret, then Engineer of the central service of the permanent way of the Orleans Railway (1). A new investigation of this question would only offer interest if it dealt with details and compared, piece by piece, the arrangements adopted by the various railways. This question might be placed on the agenda of a future session. We will confine ourselves in the present instance to the study of fluid operated cabins.

II. — HISTORICAL NOTE.

A complete historical review of the different systems for operating points and signals by supply derived from a power distribution system, has been published by one of us in the *Bulletin of the Congress* (2).

In the present instance, we will confine ourselves to a few outlined descriptions drawn up in respect to the countries covered by our report.

The first method of power distribution utilised in Europe to supplement human effort was the water-pressure system of Bianchi and Servetaz. Numerous installations of this class are at work in Italy and on a few of the French railway systems.

Prior to this, the Westinghouse Company in the United States brought out the pneumatic system. The slowness of

(1) See *Bulletin of the Railway Congress*, number for March, 1910, p. 1337.

transmission, however, soon led to the replacement of compressed air by water under pressure for setting in operation the track appliances. But this system soon gave place to an electro-pneumatic arrangement, in which electric current supplied at 16 volts was substituted for water under pressure for setting in operation and indicating the position of the track appliances. The system has been widely adopted in America and numerous examples of it are to be found in England; there is also an installation on this system in Paris at the French Eastern Railway station.

About 1902, the London & South Western Railway Company made a trial of a system in which low pressure air was used for operating and for setting in operation and indicating the position of the track appliances; the French Northern Railway Company also applied this system to their Ermont station, with the addition of pneumatic route-couplers (trajecteurs) arranged with a view to reduce the number of the levers.

It is only quite recently that entirely electrically operated installations have been adopted by some of the English and French railways and by the Belgian State Railway. Moreover, apart from this last railway, which, so far back as 1904 had a large number of applications of the Siemens and Halske system in its principal stations, the method is at the stage of undergoing comparative trials in England and in France. Amongst the electrical systems under trial in these two countries, we may mention :

In England :

The Crewe system, of which the London and North Western Railway and the North Eastern Railway each have one installation;

The Siemens and Halske system, of which two trial installations have been made — at Derby on the Midland Railway and at Didcot on the Great Western Railway; and the Siemens Brothers system, of which the first installation comprises two cabins having frames respectively of 224 and 80 levers at Birmingham (Great Western Railway).

In France :

The Taylor system, of which there is a trial installation on the Paris Ceinture Railway; the Ducousso and Rodary system in use on the Paris-Lyons Mediterranean Railway; the Bleynie-Ducousso system on trial at the St. Jean station, Bordeaux, on the French Midi Railway;

The Descubes system, recently placed on trial by the French Eastern Railway;

And, lastly, we must mention the trial recently made by the French Northern Railway of the M. D. M. system, using compressed air for operating the points and signals, and water under pressure for setting in operation and indicating the position of the track appliances.

III. — BRIEF DESCRIPTION OF THE METHODS OF OPERATING.

The greater number of these applications have been described in the technical press. We think, however, for the sake

of clearness in this report, that we can confine ourselves to a brief resumé of the methods worked out in these different systems for the operation of a set of points and of a signal as well as of the arrangement of their controlling lever-frames.

We think that this is the best method for examining these systems and thus obtaining an idea of the differences between them.

a) Bianchi and Servetaz System.

The Bianchi and Servetaz system uses water at a pressure of about 50 atmospheres as motive power operating the points and signals. The supply of water under pressure is stored in an accumulator supplied by a combined lifting and forcing pump which can be operated by hand in the case of small installations; a lever is arranged for this purpose in the cabin alongside the central apparatus. In the case of larger installations, the pump is run by a motor of 0·5 to 1·0 horse-power.

The accumulator is generally of sufficient capacity to enable fifty operations to be effected. In large installations, it will suffice for a hundred or even two hundred operations.

The pump draws the liquid from a sump into which the return conduit from the track appliances empties itself; the liquid passes through a filter so that it is freed from all impurities before being pumped a second time.

To avoid freezing of the fluid in winter, glycerine is mixed with the water; the percentage of glycerine to be added is decided according to the temperature.

Pure water is used when the temperatures are above 0° C. (32° Fahr.).

Operation of a set of points.—Figures 1, 2, 3, and 4 show clearly the various phases in the operating of a set of points. The stroke of the lever is divided into two stages. The second stage, which frees the mechanical interlocking arrangements, can only be effected after the indication of the position of the appliances has been shown in the cabin. With this object, the lever is arranged so as to be dependent on a differential piston, the slide valve of which is operated by the tongues of the points themselves.

In its thrown-over position (fig. 3) the points are only held in position by the pressure of the water against the larger piston surface. The points are not bolted in their extreme positions; those which are taken as facing points are fitted with a mechanical treadle (locking-bar) operated by the same apparatus as the points themselves; this apparatus in its normal position locks the point tongue against the point rail. This arrangement cannot be taken trailing. It may be supplemented by a mechanical detector acting on the signal transmission gear in cases where the latter is operated by wire transmission.

The two sets of points of the same track-connection (or crossover road) are operated by a single lever. In this case, the sets of points are operated in series, the operating fluid being admitted to the differential piston of the second set of points by means of the indicator slide valve of the first set of points which acts after these points have been operated; the slide valve of the second set of points sends indication of the position of the second set of points to the cabin, and permits the second stage of the movement of the lever to be effected.

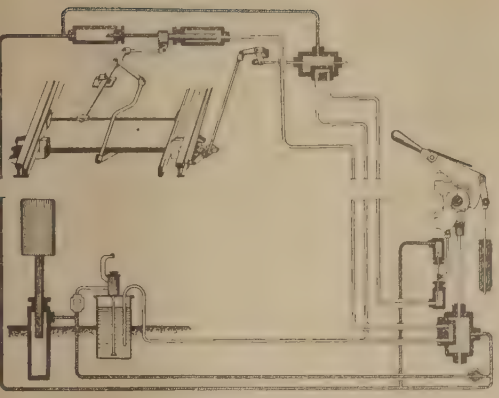

Fig. 1.
Normal position.

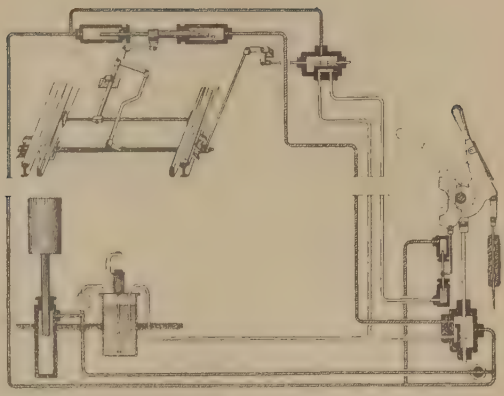

Fig. 2.

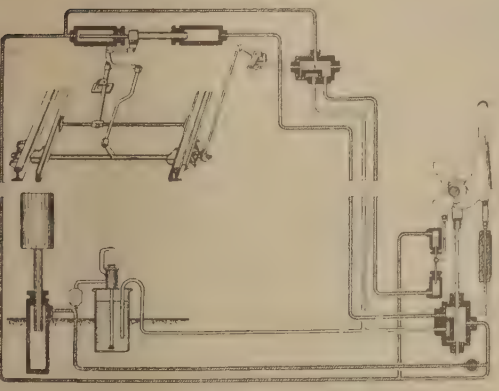

Fig. 3.
Lever thrown right over.

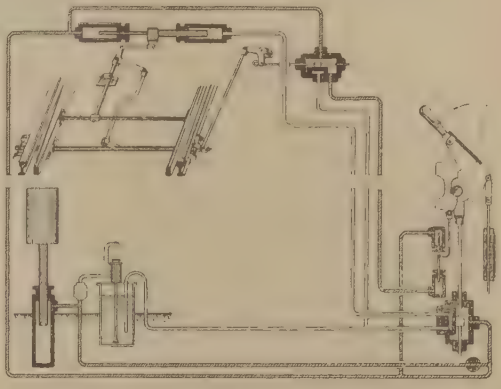

Fig. 4.
Lever thrown half-way back : points moving.

Figs. 1 to 4. — Set of points operated by the Bianchi and Servetaz system.

Operation of a signal. — The operation of a signal is shown diagrammatically in figure 5. The lever in the cabin only acts on a valve which puts the single conduit in communication with the source of water pressure when it is required to set the signal to line clear, and to exhaust when the signal is to be restored to its normal or stop position.

The operating gear consists of a single acting cylinder; the return to the stop position of the signal is performed entirely by the action of gravity.

In the case of signals at some distance

from the cabin, the operating gear is arranged close to the cabin and acts on the signal by means of a single wire transmission.

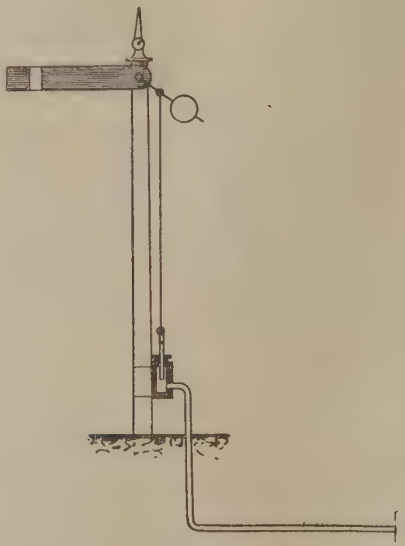

Fig. 5. — Signal operated by the Bianchi and Servetaz system.

Central apparatus. — The central apparatus for operating the appliances consists solely of the operating levers, placed side by side and connected together by a vertical interlocking frame on the Stevens system.

The admission slide valves as well as the differential pistons of the indicating appliances are arranged on the lower storey of the cabin; this also usually contains the appliances for operating the signals, the pump, and the sump.

On the French Northern Railway at the Valenciennes station, a system of hydrodynamic route-couplers has been fitted for operating the points and the signals of a complete or partial route by means of a single lever.

b) Low Pressure Pneumatic System.

The low pressure pneumatic system uses compressed air at a pressure of one atmosphere in the supply main for operating the appliances and of a half atmosphere in the conduits necessary for actuating the valves and for indicating the position of the points.

Operation of a set of points. — Figure 6 shows diagrammatically the arrangement for operating a set of points.

The movement of the lever L is divided into two stages; nevertheless the second stage of the movement is effected automatically, without assistance from the signalman, when the return from the indicator

conduit showing that the complete movement of the points has been effected, raises one of the piston p_1 or p_2 and consequently operates the slide block C of the point lever.

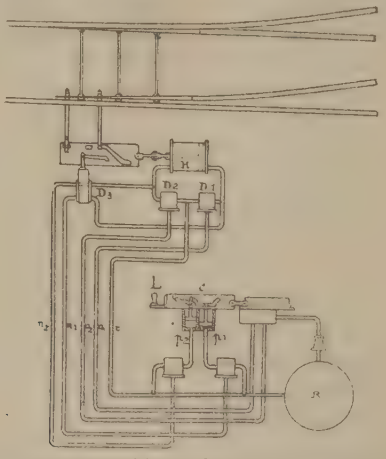

Fig. 6. — Set of points operated by the low-pressure compressed air system.

The operating gear of a set of points comprises five pipes, the conduit r from the compressed air reservoir R, two pipes $o_1 o_2$ for controlling the valves $D_1 D_2$ of the operating cylinder H and two pipes $n_1 n_2$ for indicating respectively the normal position and the thrown-over position of the points; this indication is ensured by the operation of the distributing valve D_3 connected to the points.

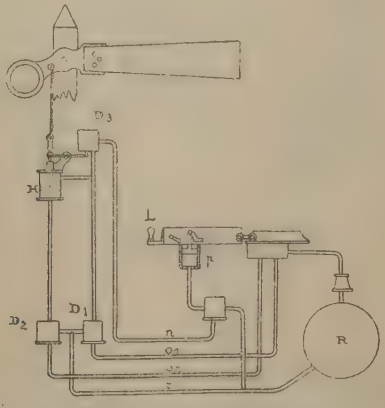

Fig. 7. — Signal operated by the low-pressure compressed air system.

Operation of a signal. — The operation of a signal is effected by means of a single acting cylinder; when a signal is to be set to line clear, the operation of the lever in the cabin is made in one stage, and in the case of the return to normal or stop position, in two stages, the second stage being performed automatically. Figure 7 shows diagrammatically the arrangement adopted. It is analogous to that adopted for operating the points, but has only a single pipe *n* for indicating the position of the signal when at danger.

Central apparatus. — The levers of the central apparatus work horizontally; they are interlocked with each other by means of a vertical frame on the Stevens system.

In France where an application of the low-pressure operating system has been made at Ermont, the individual actuating gear of the points and signals has been replaced with simultaneous operating gear for all the points and signals of a route by means of one or more pneumatic route-couplers analogous to those which have been employed in the hydro-pneumatic installations and in particular those at Valenciennes.

c) The M. D. M. Hydro-Pneumatic automatic route-combiner System.

The M. D. M. automatic route-combiner uses compressed air at a pressure of from 2 to 4 atmospheres for operating the points and the signals, and water at a pressure of from 5 to 12 atmospheres for operating the admission valves of the motors and the indicators of the appliances on the track.

Operation of a set of points. — Figure 8 shows a longitudinal section of the motor for a set of points.

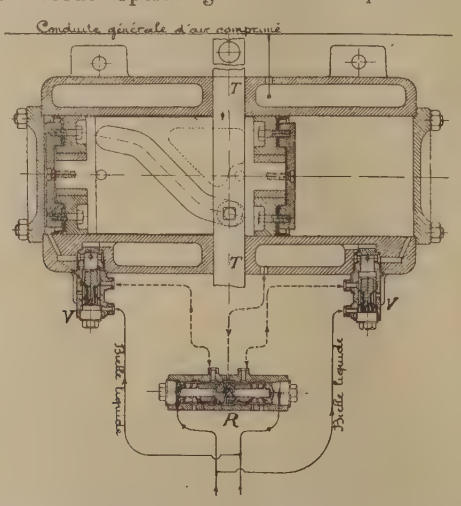

Fig. 8. — Operating gear for a set of points : M. D. M. system.

Explanation of French terms : Conduite générale d'air comprimé = Compressed air supply main.
Bielle liquide = Fluid connecting-rod.

It consists essentially of a bored cylinder with a jacket which serves as an air reservoir. Two pistons move air-tight in the cylinder and are connected to a slide in which a groove is formed; this slide drives the operating rod T which is connected to the point tongues.

Figure 9 shows diagrammatically the hydro-dynamic connections for a set of points.

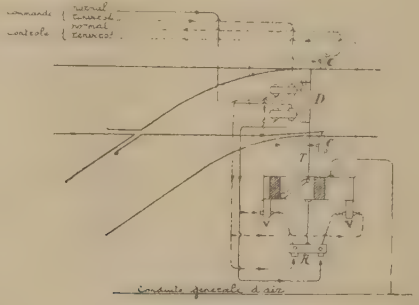

Fig. 9. — Diagram of the hydraulic connections : M. D. M. system.

Explanation of French terms : — Commande normale = Flow for operating normal. — Commande renversée = Flow for operating thrown over. — Contrôle normal = Flow for indicating normal. — Contrôle renversé = Flow for indicating thrown over. — Conduite générale d'air = Compressed air supply main.

The compressed air contained in the jacket is admitted alternately behind the one or the other of the pistons by means of a relay R and of the two valves V set in action by the hydro-dynamic mains coming from the operating keyboard in the cabin.

Each set of points is fitted with a switch D and point indicators C, which serve to show the indication of the position of the points in the cabin.

Operation of a signal. — The operation of a signal is effected by means of a single acting motor acting either directly on the arm of the signal, or at a distance by means of a single wire transmission.

This compressed-air motor is set in motion by means of a hydro-dynamic valve analogous to that used for operating the motors for the points.

Central apparatus. — The central apparatus consists essentially of :

1° An operating keyboard consisting of horizontal rows and vertical columns; each row corresponds to an arrival route and each column to a departure route, or vice versâ. At the intersection of the rows and of the columns, keys are arranged for operating the corresponding routes corresponding to the arrival road and departure roads to which they refer. The same key serves for two routes in opposite directions. According to whether the key is turned vertically or horizontally, the arrival signal or the departure signal is cleared after the signals affected by the route have been indicated in the cabin as being in the positions which they should occupy.

The keys are interlocked with each other in such manner as to prevent the simultaneous making of two routes which taken in combination with each other would be unsafe.

2° A *laboratory* consisting of a series of valves and conduits arranged on the ground floor of the cabin. It is here that the multiplication of the operations and the summing of the indications is effected. Figure 10 shows the arrangement of this laboratory diagrammatically.

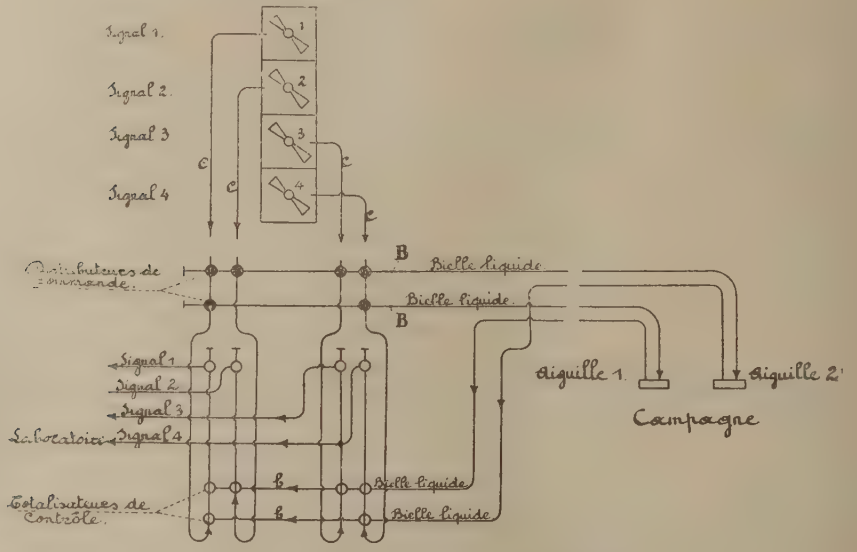

Fig. 10. — Diagram of the arrangement of hydraulic pipes and connections in the cabin : M. D. M. system.

Explanation of French terms : Signal = Signal. — Bielle liquide = Fluid connecting rod. — Aiguille = Set of points. — Campagne = On the track (the other details are in the cabin). — Distributeurs de commande = Valves of operatung gear. — Laboratoire = Laboratory. — Totalisateurs de contrôle = Apparatus for securing the indications received (totalizer).

d) The Westinghouse Electro-Pneumatic System.

The Westinghouse Electro-Pneumatic System employs compressed air at a pressure of about 5 or 6 atmospheres for operating the track appliances. The setting in operation of the track appliances and the indication of their position are ensured by means of an electric supply at about 16 volts.

The air compressors are generally operated by means of electric motors with automatic starting gear, so arranged as to start the motors when the pressure falls below a certain limit (4·5 atmospheres). As a general rule, a connection is fitted at some point on the air supply main, in order to permit of a supply being obtained

from the brake pump of a locomotive in case the regular pneumatic pump or its driving gear fails.

The electric supply is derived from two Tudor accumulator batteries which are alternately put in work and charged by a transformer group.

Operation of a set of points. — Figure 11 shows the pneumatic portion of the operating gear. The motor portion of the apparatus consists of a double acting cylinder, the piston of which is connected directly to the point tongues. The compressed air is led from the main to one end of the cylinder by means of an electrically operated valve, while the other end of the cylinder is opened to exhaust. An auxiliary reservoir containing a reserve of compressed air sufficient for several operations is fitted near each motor.

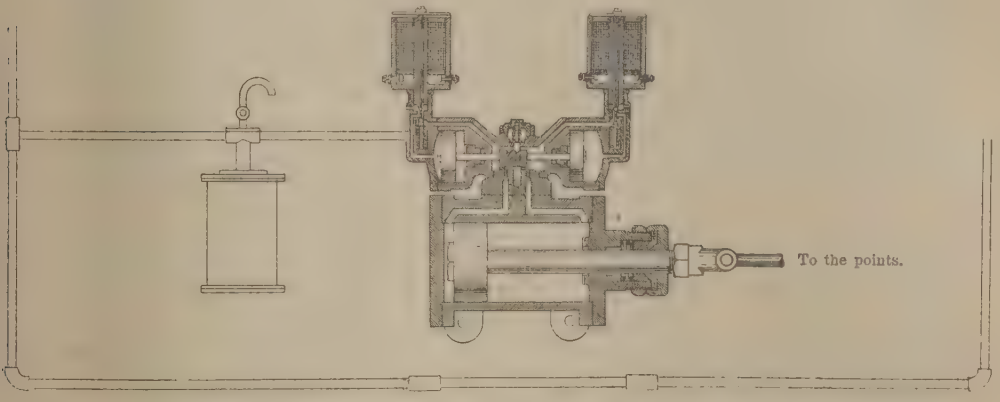

Fig. 11. — Operating gear for a set of points, Westinghouse system.

The points cannot be taken trailing. The motor apparatus first operates a bolt which locks the operating bar of the points before and after the points have been operated.

Figures 12, 13, 14 and 15 show diagrammatically the electric connections which connect the lever in the cabin to the motor on the track.

The connections between the operating gear and the lever consist of five wires; two are for operating, two are for indicating the position of the appliances, and one is the common return wire. The stroke of the lever is divided into two stages : the first stage of the stroke makes connection between the electric supply and wire 2; the operating electro-magnet R is excited and the motor apparatus is put in movement. The points operate the point tongue contacts b_1 and b_2, and, at the end of their stroke, connect wire 2 with wire 4; the current is shunted by this switch and excites the electro-magnet r in the cabin; the armature of this electro-magnet frees the lever and allows it to travel to the end of its stroke; this second movement operates the switch c_2.

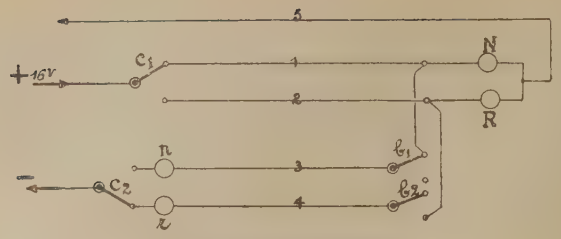

Fig. 12. — Normal position.

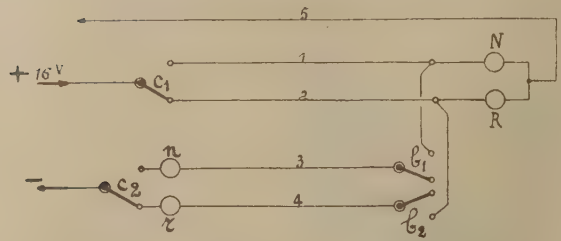

Fig. 13. — First stage of the operation : points moving.

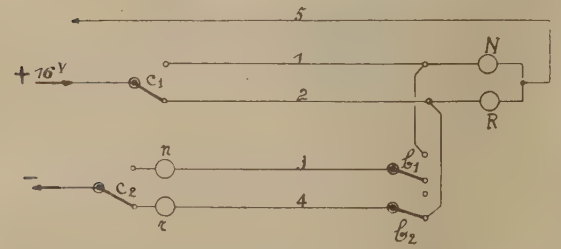

Fig. 14. — Points thrown over : released.

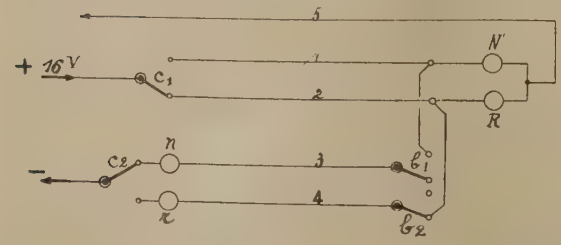

Fig. 15. — Thrown over position.

Figs. 12 to 15. — Diagrams of the electric connections for operating a set of points by the Westinghouse system.

A continuous current flows in each of the operating wires corresponding to the position of the lever and of the points.

Operation of a signal. — The operation of a signal is effected by means of a single-acting cylinder. Compressed air is admitted to the cylinder by means of an electrically operated valve; the return to normal or stop position is made by gravity, when the operating electro-magnet is no longer excited; the valve in falling on its seat opens the connection from the cylinder to exhaust.

The electric connections of the operating gear are shown diagrammatically in figures 16, 17 and 18.

By pressing on the latch handle of the lever, the signalman closes the cutout c_1 and the current excites the electro-magnet e, which frees the lever. The lever can then be moved, and closes the cut-out c_2. The electric current excites the operating electro-magnet A.

At the moment when the signal is set to line clear, the cut-out s opens the circuit of the electro-magnet e.

The operation of returning to normal or stop position is divided into two stages; the lever in the first stage opens

the cut-out c_2 and opens the circuit through the electro-magnet A; the signal being returned to normal or stop position by gravity, closes the cut-out s; the electro-magnet e is then excited by a current, attracts its armature, and allows the second stage of the travel of the lever to be performed.

Central apparatus. — The central apparatus consists of the operating levers for the points and for the signals arranged side by side and interlocked by means of a vertical interlocking frame on the Stevens system.

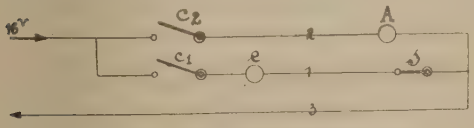

Fig. 16. — Normal position.

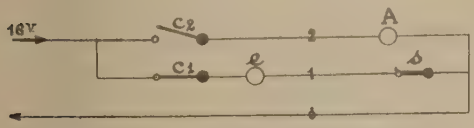

Fig. 17. — First stage of the movement of the lever.

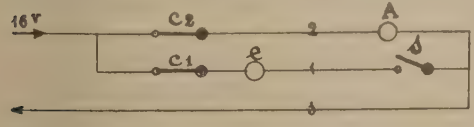

Fig. 18. — Signal at line clear.

Figs. 16 to 18. — Diagrams of the electric connections for operating a signal by the Westinghouse system.

In some cases, for operating the two signals protecting a single route, which can sometimes be run over in either direction, signal levers having three positions are used : in the normal position they are vertical and can be thrown over backwards for traffic in the one direction, and forwards for traffic in the other direction.

This arrangement has been adopted for operating the points at the Paris station of the French Eastern Railway; the direction in which the routes are to be run over is determined by the position of the levers capable of occupying three positions; this has permitted a simplification in the locking frame by utilizing to a great extent route-interlocking amongst the points according to whether they are run through in the one direction or in the other direction.

e) Webb and Thompson Electric System (Crewe System).

Operation of a set of points. — The Webb and Thompson system makes use of series-wound motors with single field-magnets for operating the points. The change of direction of rotation of the motor, necessary for ensuring the operation of the points in both directions, is obtained by reversing the direction of flow of the current in the armature by means of a switch operated by the lever of the central apparatus. The scheme of electric connections comprises six wires between the points and the cabin, as is shown in figures 19 to 22.

The stroke of the lever is divided into two stages. The first stage of the stroke operates the switches c_1, c_2 and c_3; the wire 1 is connected to the wire 3, and the wire 2 is connected to the negative pole of the battery. The same occurs with the wires 5 and 6.

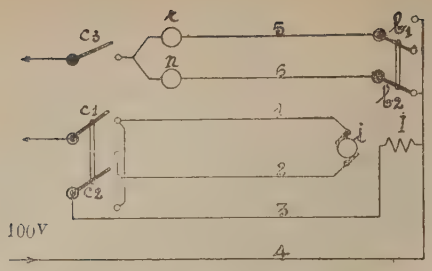

Fig. 19. — Normal position.

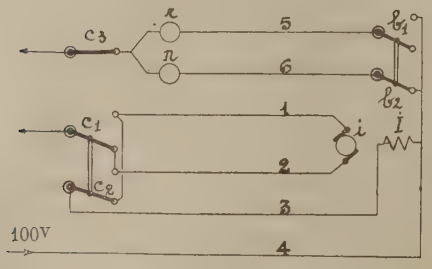

Fig. 20.
Lever thrown half-way over : points moving.

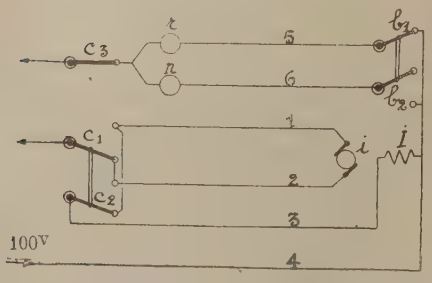

Fig. 21. — Point thrown over : the lever is released for completing the second stage of its movement.

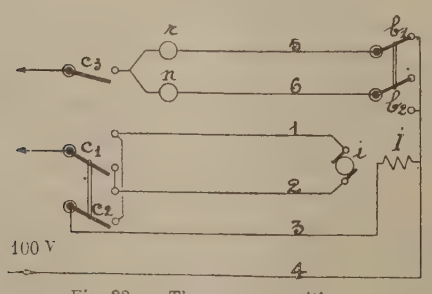

Fig. 22. — Thrown over position.

Figs. 19 to 22. — Diagrams of the electric connections for operating a set of points by the Webb and Thompson (Crewe system).

The motor revolves, and, having arrived at the end of its travel, operates the switch $b_1 b_2$; this insulates the wire 6 and connects the wire 5 to the wire 4 and to the positive pole of the battery. The electro-magnet r is excited and the lever can complete the second stage of its travel; this latter movement frees the mechanical interlocking gear and insulates the wires 1, 2, 3, 5 and 6.

The current necessary for operating a set of points is 20 amperes at about 100 volts.

A mechanical coupling is arranged between the motor and the points by means of which the motor is disconnected from the points when the latter have been operated and bolted, and turns free until the signalman has effected the second stage of the movement of the lever.

The points cannot be taken trailing.

Operation of a signal. — The signals are operated by means of single-acting solenoids. The return to normal or stop position is made by gravity.

The current passes through a switch, operated by the signal lever, and through detectors indicating the position of the point tongues in cases where the points are taken facing. At the end of its travel, the signal arm operates a switch which inserts a resistance in the circuit reducing the quantity of current to that necessary for retaining the signal in its line clear position.

The current necessary for operating the signal arm is 15 amperes at 100 volts; for maintaining the signal in its line-clear position 2 amperes only are required.

Central apparatus. — The operating

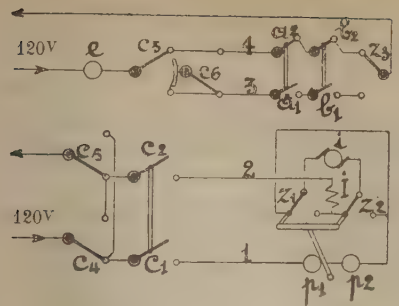

Fig. 23. — Normal position.

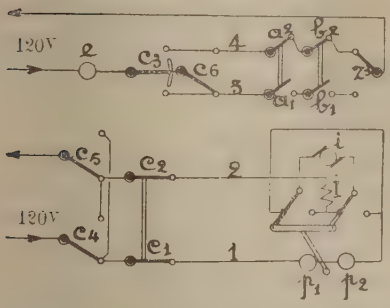

Fig. 24. — Lever thrown half-way over.

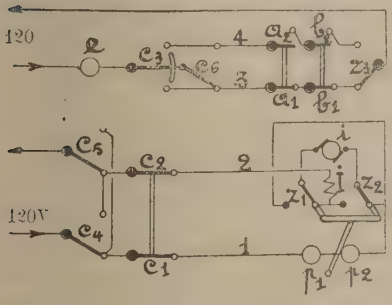

Fig. 25. — Points thrown over.

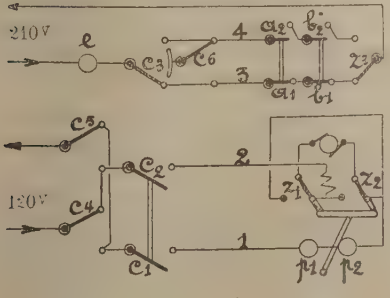

Fig. 26. — The thrown over part.

Figs. 23 to 26. — Diagrams of the electric connections for operating a set of points by the Ducousso and Rodary system.

levers, which are of the form of small Saxby levers, are arranged in two rows, one above the other, and operate, by means of vertical rods, bell-cranks connected to mechanical interlocking arrangements, also a series of carbon contacts for currents of large quantity, and lastly the interlocking arrangement for the indication of the position of the point tongues. The locking frame and all the electric portion of the installation are arranged below the floor-boards of the cabin.

The total height of the apparatus is only 3·30 metres. The connections between the central apparatus and the appliances on the track are formed by means of cables covered by metallic casing.

f) Ducousso and Rodary Electric System.

Method of operating the points. — The Ducousso and Rodary electric system also uses series-wound electric motors with single field-magnets for operating the points; the change of direction of running of the motor is obtained by means of a switch placed at the points and connected to the armature of a polarized relay.

The electric connections comprise 5 wires shown diagrammatically in figures 23 to 26.

The stroke of the lever is divided into two stages. The switches c_1, c_2 and c_3 are operated by the lever during its first stage of movement. They connect respectively the wires 1 and 2 to the two poles of the electric supply and form a circuit which flows through the polarized relay from p_1 to p_2; this relay, thus excited, attracts its armature which operates the switch z_1, z_2, z_3 and reverses the flow of the current in the fields I; the motor revolves and actuates the points.

When the points are in the thrown-over position, the point contacts a_1, a_2, as also the switch b_1, b_2, close an electric circuit and allow a current to flow which excites the electro-magnet e; the second stage of the travel of the operating lever can then be effected; it results in the movement of the switches c_1, c_2 and c_3 as well as of the switches c_4, c_5 and c_6 and prepares for the movement of the points in the opposite direction.

The points cannot be taken trailing; nevertheless in order to allow of the points being taken trailing, a Perdrizet spring is inserted between the points and the operating rod [1].

Operation of a signal. — The signals are operated by means of series motors running in one direction only; the signal is restored to normal or stop position by the action of gravity.

The arrangement of the electric connections comprises three wires. The stroke of the lever is effected in a single stage for setting to line clear, and is divided into two stages for setting to normal or stop position; the second stage of this operation freeing the interlocking arrangements can only be effected after the indicator in the cabin has shown that the signal has resumed its normal or stop position, by the flow of the indicator current. A mechanical ratchet gear acting directly on the balance weight with which the signal is fitted, prevents the signal from being put accidentally to line clear after it has been returned to its normal or stop position.

Central apparatus. — The central apparatus consists essentially of small levers of the Saxby type interlocked with each other by means of a Stevens frame.

g) Bleynie-Ducousso System.

The Bleynie-Ducousso system utilizes the same appliances as the system which we have just examined for the operation of the points and signals. The essential difference consists in the operating gear which comprises route levers, instead of individual levers, for operating all the points involved in the route by means of a single lever. The signals are, moreover, also operated by single levers interlocked with the route levers. The stroke of the route levers is divided into two stages, the second stage of the stroke can only be performed after all the points which require to be shifted for the completion of the route have been indicated as occupying the correct position by the flow of the indicator current. With this object, the indicator electro-magnet e (fig. 23) is duplicated for each set of points and the armature of each of these indicator electro-magnets operates a contact inserted in the circuit of the locking electro-magnet of the route lever. The second stage of the stroke of the route lever interrupts all the indicator circuits and closes a contact inserted in the operating circuit of the corresponding signal.

The stroke of a signal lever is made in one stage, when the signal is being set to line clear; moreover, if the route is protected by two signals (a stop signal and a

---

[1] See " The electric operation of points and signals " by L. Weissenbruch (*Bulletin of the Railway Congress*, number for August, 1904, p. 651).

distant signal), the two signals are operated by the same signal lever, the stroke

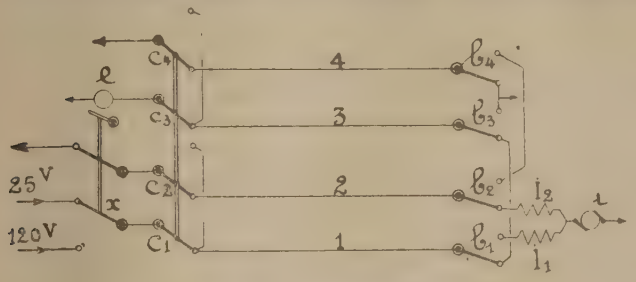

Fig. 27. — Normal position.

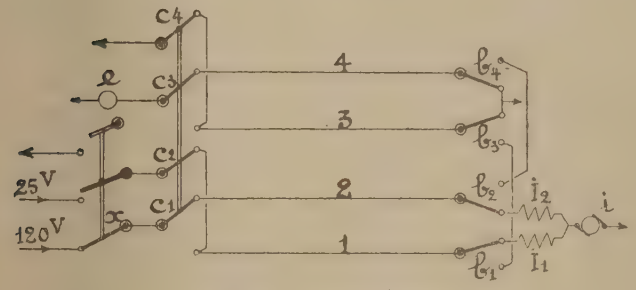

Fig. 28. — Points moving.

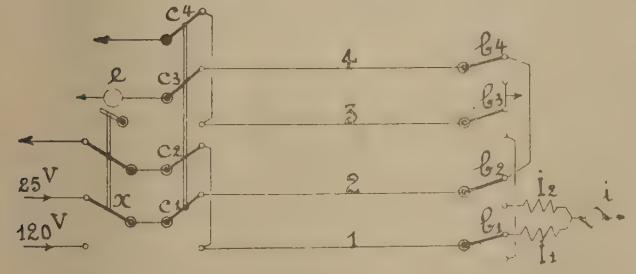

Fig. 29. — Thrown over position.

Figs. 27 to 29. — Diagrams of the electric connections for operating a set of points by the Siemens & Halske system.

of which is divided into two stages, the second stage of the stroke having the effect of putting the distant signal to line clear; this cannot be effected unless the first or danger signal is actually at line clear. The setting to normal position of the signal lever is effected in two stages, as in the Ducousso and Rodary system.

The route levers are mechanically interlocked with each other so as to avoid the simultaneous formation of two routes which in combination with each other would be unsafe.

In case of failure, a special frame is used, normally kept sealed; this allows the points to be operated singly.

h) Siemens and Halske System.

For operating the points and signals on the Siemens and Halske system series wound motors are used, with double field-magnets to obtain rotation of the motor in the one or in the other direction according to whether the one or the other of the fieldmagnets is excited by the current.

It is, moreover, arranged with a permanently flowing indicating current indicating the position of the points and of

the signals; the current used for this purpose is at a lower voltage than that used for operating the appliances.

Operation of a set of potnts.—Figures 27, 28 and 29 show diagrammatically the electric connections for the operation of a set of points. They comprise four wires connecting the appliance and the operating handle. The operation is performed in one stage. The indicator current at 25 volts flows normally through the wire 1, the switch b_1 depending upon the position of the operating lever, the switch b_3 depending upon the position occupied by the point tongues, the wire 3, the switch e_3 and the indicator electro-magnet e. The wires 2 and 4 through which the current does not flow, are connected to earth at one or both of their ends. It follows from this arrangement that no contact made with the wires can set the points in motion or give a wrong indication on the indicator.

Throwing over the lever results in changing the position of the switches c_1, c_2, c_3 and c_4. The electro-magnet e is short-circuited by the wire 4; the economising switch x substitutes current at 120 volts for the 25 volt current.

At the commencement of the operation, the switches b_1 and b_3 are thrown over allowing the points to be reset to their normal position without waiting for the completion of the movement. At the end of the operation, the switches b_2 and b_4 are thrown over and cause the 120 volt current to pass through 2, b_2, b_4, 4 and e; this electro-magnet being excited, attracts its armature which operates the switch x, and replaces the 120 volt current by current at 25 volts. The wires 1 and 3, which are not in use, are earthed.

The quantity of current used for operating is about 2·5 to 3 amperes at 120 volts; for indicating, it is 0·06 amperes at 25 volts.

Operation of a signal.— The signals are operated by means of appliances analogous to those used for operating the points; this renders it possible to avoid having recourse to the action of gravity for the return to normal or stop position. The signal is electrically operated both in the case of the return to normal or stop position and when set to line clear.

The operating gear acts on the signal disk or on the arm of the semaphore through an electric coupling which consists essentially of an electro-magnet, the armature of which, when excited, makes connection between the operating gear and the signal proper.

The coupling circuit passes through contacts which depend upon the position of the armature of the electro-magnets of the indicators of the points affected by the route.

Rupture of this circuit causes the signal to be set automatically to normal or stop position; this can also be effected by means of a rail contact actuated by the train; for this purpose, it is merely necessary to insert in the coupling circuit a contact depending on the position of the armature of a relay connected to this rail contact. It will be readily understood that still further additions may be required and easily realized by means of the coupling current for the signals. The quantity of current used for this purpose is about 0·25 amperes at 25 volts.

Central apparatus. — The central apparatus consists essentially of small hand levers for the operation of the points and of the signals, and also of auxiliary handles for the routes. The small hand levers for the points are interlocked mechanically with the hand levers of the routes, which in their turn interlock mechanically the hand levers of the signals. In appliances of the latest type, only the hand levers for points and for routes are usually fitted; these latter are operated in two stages, the second stage serving to set the signal to line clear.

The main function of the route hand levers is to retain the interlocking of the points after the signal has been thrown to normal or stop position behind the train; they also effect the selection of the various signals which can be given by a single semaphore mast; for this purpose they operate electric contacts, inserted in the coupling circuits of the signals, which permit the latter then to be operated by a single operating gear and a single hand lever in the central installation. They may also be interlocked by the train itself, in such manner as to remain locked during the whole period the train is running over them, being freed only after it has run over a rail contact acted on only by the last pair of wheels (see section B).

i) Siemens Brothers' System.

The Siemens Brothers' system which has been fitted some little time now on the Great Western Railway at Birmingham, uses motors with double field magnets for operating the sets of points, as in the previously described system, and single-acting appliances for operating the signals.

Operation of a set of points. — Figures 30 to 33 show diagrammatically the electric connections consisting of four wires. There is no permanently flowing indicator current, and the operation of the hand lever is effected in two stages. The first stage operates the cut-outs x_1 and x_2 and the switches c_1 and c_2, and completes the 120 volt circuit x_1, c_1, 2, b_2, I_2, and i to earth; at the commencement of the operating of the set of points, the switches b_1 and b_3 are operated and connect the wire 1 to the field-magnets I_2, and the indicator wire 3 to earth; at the end of the operation the switches b_2 and b_4 are operated, and complete an electric circuit through which a 120 volt current passes, exciting the electro-magnet n, the armature of which frees the operating lever; the second stage of the movement of the lever restores the cut-outs x_1 and x_2 to their normal position.

Operation of a signal. — The principle employed for the operation of a signal is analogous to that of the Ducousso and Rodary system. Figures 34 to 38 show diagrammatically the electric connections which comprise only two wires for each signal arm, the return being rendered unnecessary by earthing the negative pole of the battery.

The operation of the hand lever is effected in one stage for setting the signal to line clear; it operates the cut-outs x_1 and x_2 and the switch c_1 and c_2; current flows through the wire 1, excites the coupling electro-magnet A, and causes the motor to revolve. This circuit includes the contacts d, d', operated by the tongues of the points affected. At the commencement of the movement of the signal, the

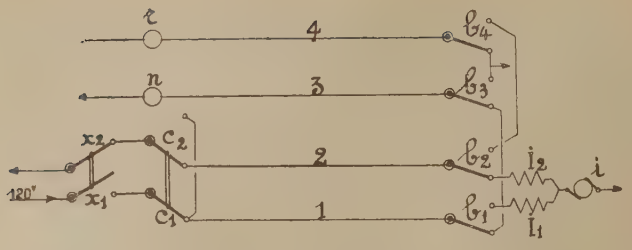

Fig. 30. — Normal position.

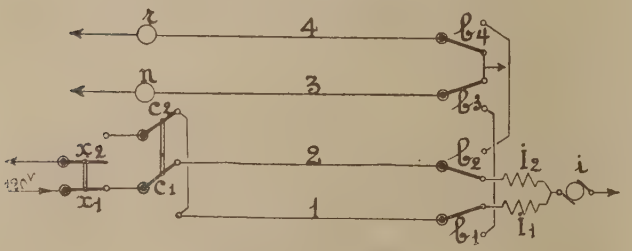

Fig. 32. — Points moving.

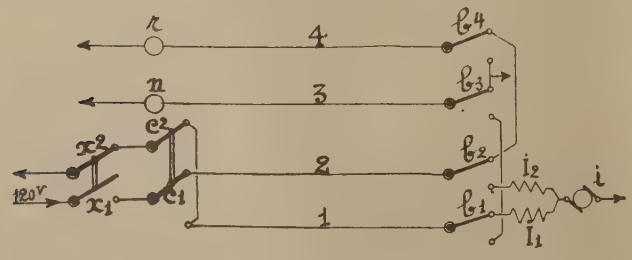

Fig. 33. — Thrown over position.

Figs. 30 to 33. — Diagrams of the electrical connections for operating a set of points by the Siemens Brothers' system.

switch b_2 is operated and the wire 2 is insulated from earth; when the signal is set to line clear, the switch b_1 is operated and interrupts the motor circuit. The arm is retained at line clear by the coupling circuit A.

To return the signal to normal or stop position the switch c_1 and c_2 is operated by the first stage of the movement of the hand lever; the coupling current A is interrupted and the arm falls back under the action of gravity, operating the switches b_1 and b_2; the locking electro-magnet e is excited by a current and frees the operating lever which can be thrown back to the end of its travel; this operates the cut-outs x_1 and x_2.

Central apparatus. — The central apparatus comprises the levers for operating the points and those for operating the signals, interlocked with each other by means of a vertical locking frame. The arrange-

ments of the central apparatus are so combined as to take up the minimum of space; the width of the apparatus only measures 30 centimetres (1 foot), and the levers are spaced only 5 centimetres (2 inches) from each other.

Figs. 34 to 38. — Diagrams of the electric connections for operating a signal on the Siemens Brothers' system.

j) Taylor's System.

The Taylor system, of which an installation has been fitted on trial in France on the Paris Ceinture Railway, also effects the operation of the points and of the signals by means of series-wound motors with single field magnets.

Operation of a set of points. — The operation of the point lever is effected in two stages. The indication of position of the appliances which is of positive character is obtained at the end of the travel by short-circuiting the motor, which then works as a dynamo, producing current which frees the lever for its second stage of operation.

Figures 39 to 42 show diagrammatically the electric connections which consist of three wires, two for operating and one serving as the common return wire.

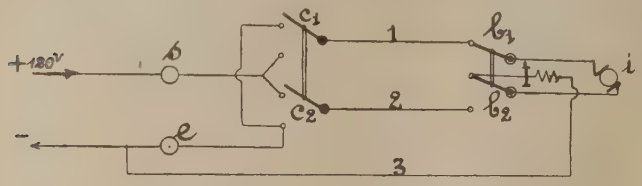

Fig. 39. — Normal position.

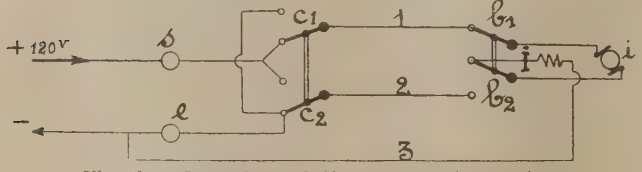

Fig. 40. — Lever thrown half-way over : points moving.

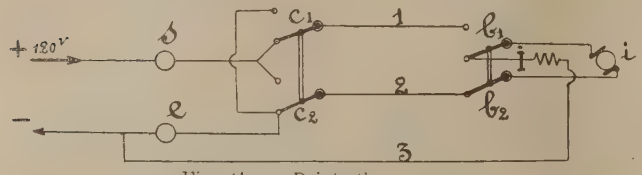

Fig. 41. — Points thrown over.

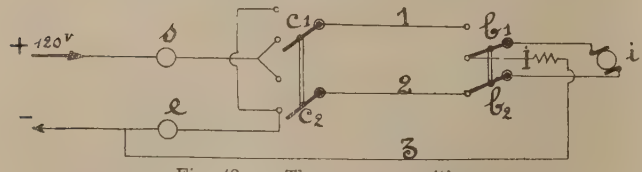

Fig. 42. — Thrown over position.

Figs. 39 to 42. — Diagrams of the electric connections for operating a set of points by the Taylor's system.

The first stage of the movement of the lever operates the switches c_1 and c_2 and completes the operating circuit in which current flows through the safety electro-magnet s, the wire 1, the switch b_1, the armature i, the switch b_2, the field magnets I, the wire 3 to the negative pole of the battery. At the end of the travel of the motor, the switches b_1 and b_2 are operated, short-circuiting the motor by the wires 2 and 3 and short-circuiting the indicator electro-magnet e; the current generated by the motor when running as a dynamo excites the electro-magnet e; freeing the second stage of movement of the hand lever; this second stage of the movement maintains the switch c_1 and c_2 in position, and insulates the wires 1 and 2.

The armatures of the electro-magnets s and e are connected to each other.

Operation of a signal. — The operation of a signal is effected under conditions absolutely analogous to those used in the

Ducousso and Rodary and the Siemens Brothers' systems; the signal is returned to normal or stop position by the action of gravity alone, but the interlocking gear is only freed after the indicator current, the circuit of which is completed at the moment at which the signal returns to its normal or stop position, has allowed the second stage of the movement of the signal lever to be effected.

Central apparatus. — The central apparatus comprises horizontal slides interlocked with each other by means of a Stevens locking frame with inclined tappets. This arrangement makes the handling of the levers somewhat heavy when compared with that of the other systems.

k) Simplified Electrical Systems.

In order to render more easy the comparison of the different systems using electrical circuits which we have enumerated, we have shown the connections diagrammatically with a simplified notation which has enabled them to be reduced to a very few lines. Figures 43 to 48 show for each of the systems the normal position of the cut-outs and switches. The signs and abbreviations used are shown on the next page.

IV. — COMPARISON OF THE VARIOUS SYSTEMS.

The following general deductions can be drawn from the abstracts which we have just given.

Operation of points. — In fluid-operated cabins, the operation of points is effected actually either by means of water under pressure, or of compressed air, or of electricity.

The advantages and disadvantages of these different methods of control at a distance are too well known for us to enter into lengthy examination of them. In the case of water under pressure and of compressed air, piston motors are used in which the to and fro movement can be transmitted directly to the point tongues or to the signals, whereas in the case of electricity, the use of solenoids has been generally rejected, and motors are used in which a movement of rotation is transformed into a movement of translation by means of gearing consisting of toothed wheels and a rack. But the apparent advantage offered by water and compressed air is largely compensated by the disadvantages inherent to these two methods of power transmission. The disadvantages are due to the leakages which occur at the joints of the pipes and at the piston rings, difficulties in affecting the replacement of one motor by another in case of failure, and difficulty in effecting the maintenance of these appliances, and more particularly in the case of water under pressure, the care which must be taken to prevent freezing in winter. It should further be added that the differential principle when applied to some installations is dangerous, because a point tongue may be set in movement unintentionally through a fracture of the supply main.

From all these points of view, it is indisputable that electricity offers the greatest number of advantages in practice.

Our colleague in America, Mr. Carter, states the same, although compressed air has found very many applications in that country.

In a new system now on trial at Praed Street Junction and at Aldgate on the Metropolitan Railway in London — the Johnson system — the electric motor sets in motion a column of mineral oil which acts on a differential system connected to the points to which it transmits its movement directly.

This appears to be a complication which s not likely to obtain many applications. This system, moreover, utilises the differential principle which gives rise to a certain amount of risk.

Indicators. — All the systems in use include indicators for showing the position of the track appliances. This indication is generally effected electrically, which enables the indication to be performed instantaneously when the track appliance has come to the end of its travel.

In the low pressure pneumatic system, the indication requires as much as twenty seconds. In the system using water under pressure, the hydraulic indicator, which frequently takes from ten to twelve seconds to effect the indication has been retained. The M. D. M. system utilizes hydraulic indicators by means of a fluid connecting rod which is relatively speedy.

The fault which might be found with the electrical indication is that it might have the serious disadvantage of giving the indication at a wrong time in the cases either of crossing of the wires or of defective insulation of the conductors, and it would seem that the attention of all the designers has not been equally carefully given to this very important point. We ought, in fact, to note that with the exception of the Siemens and Halske system and the Siemens Brothers' system, no special precaution has been taken for guarding against the consequences of

contacts made by crossed wires whether momentary or permanent. In both the latter systems, the danger of a false indication due to crossing of the wires is rendered impossible owing to the earthing of the negative pole of the battery, which enables all those portions of the appliances most necessary in respect to safety, to be connected to earth; such are the armature of the motor, the indicator electro-magnets and the coupling electro-magnets of the signals, the contacts closed by the point tongues, etc., as well as those wires through which no current is flowing. It follows from this arrangement that *in no case* can defective insulation of a conductor or crossing of the wires cause dangerous indications : these two classes of disarrangement can, in fact, only have the consequence of short-circuiting to earth those portions on which the safety of the systems depends. It might further be objected that the earth contacts in question could also become insulated, but it would be easy to apply electric tests to these if it were desired to guard against this extremely improbable event.

In general terms, the indication is effected positively or is maintained continuously. In the first case, it acts only at the end of the stroke of the appliance operated and ceases immediately after the second stage of the movement of the lever has been effected, the second movement being impossible until the indication takes effect. It is, in fact, essential to operate the levers in two stages when no permanently flowing indicator current is used, in order to avoid liberating the mechanical interlocking before the indication of the operation has been received.

The operation of the lever in the cabin in two stages is therefore an *inevitable* consequence of the positive control.

In the second system, which uses a permanently flowing indicator current, the operation of the lever can be effected in a single stage, and constant electric relations are maintained between the position of the point tongues and their actuating apparatus on the one hand, and the lever in the cabin on the other hand. This relation can also be utilized to prevent the setting to line clear of signals before the position of the points affected has been indicated; in this manner, it is very simple to obtain the detection of the points as required in the most modern specifications, particularly by the Board of Trade in England and by the State in Belgium.

On the Paris Ceinture Railway on which the Taylor system has been fitted on trial, the Company has required the addition of the Hall Automatic Block system with point tongue detectors in order to assure the same degree of safety as is obtained in Belgium by the permanently flowing indicator current.

Lastly, we think we should mention that at Yarnton Junction on the Great Western Railway, an electrical system for operating points and signals has been recently applied which makes use of a permanently flowing indicator current and consequently allows of the operation of the levers in a single stage.

Operation of a signal. — As a general rule in France and in England, the signals operated from fluid operated cabins are only actuated by single-acting appliances; the return to normal or stop position is effected in each case by gravity alone. All the systems employ the positive indica-

tion showing the setting to normal or stop position of the signal, and this requires that the operation of the signal lever for its return to the normal position should be effected in two stages. The Belgian State Railway on the other hand, makes use of double-acting appliances which obtain a degree of safety analogous to that obtainable with mechanical double-wire transmission in conjunction with automatic return to normal or stop position in the event of the breakage of a wire; this latter condition is obtained by an electric clutch gear, interposed between the signal and the actuating gear. Moreover, in new installations, an electrical interlocking is arranged between the position of the signal and the auxiliary route-lever in such manner that the latter can only be returned to its normal position — and consequently free the mechanical interlocking of the point levers — when the signal has been previously and effectively returned to its normal or stop position.

Arrangements of central apparatus. — The central apparatus generally consists of individual operating levers for operating the points and the signals. The Siemens and Halske system comprises in addition the auxiliary route-levers; but as we have already shown, these levers are used to economise signal levers by making a selection between the various indications which could be given by a single semaphore, and actually they replace the numerous levers which would be necessary if each arm and each direction number required to be operated specially.

In France several Companies and in particular the French Midi Railway, the French Eastern Railway and the French Northern Railway are following up the trials made and abandoned (1) in Germany in 1895 of the appliances of Westend, Untertürkheim and Dresden, for operating all the points and signals of one route by a single lever. We have already briefly described the general principle of the Bleynie-Ducousso system, which has been designed with this object and applied at the St. Jean station at Bordeaux (2). We have also mentioned in the same connection, the arrangements used at the Ermont and Valenciennes stations on the French Northern Railway. The general principle on which these arrangements are based is as follows :

A route is settled when the three following factors are known : the arrival road, the departure road and the direction of running. Now there are always a certain number of manœuvres which have one or two of these factors identical; consequently, in allotting a certain lever to a definite factor, this lever can be used indifferently for all manœuvres which include this factor. It follows that it is only necessary to provide one lever either for a complete route, or for a portion of a route, which will operate the whole of the points and signals affected.

The Descubes system, on trial on the French Eastern Railway, is still more radical in respect to the number of levers which it uses. The number of levers is, in fact, equal to the sum of the number of arrival roads to the zone protected by

---

(1) See « The Electric operation of points and signals, etc. ». (*Bulletin of the Railway Congress*, August, 1904, p. 651.)

(2) The German patent No. 83559 taken out by Siemens Brothers' but now expired, we believe, expresses this principle in terms remarkably similar to those used in Mr. Bleynie's specification.

the cabin, added to the number of departure roads from that zone. Any route is made by operating two levers corresponding to the ends of the route desired. These levers can occupy three positions, one normal and two thrown over. To make a route from A to X the signalman first operates the lever X by throwing it over towards him, and afterwards the lever A by throwing it over towards him through its first stage of travel; when the points have moved the indicator current is completed and unlocks lever A; the signalman can then complete the second stage of movement of the signal, which sets the corresponding signals to line clear. The operation of the points and of the signals is effected by means of electric motors.

Finally, quite recently the French Northern Railway have put on trial at their Paris station, a system of route levers — the M. D. M. automatic route-combiner — which, by its keyboard certainly affords the smallest operating board, and that which is the easiest to operate, imaginable. A brief description of this keyboard is given in the *Bulletin of the Railway Congress* (1).

The trials to which these new arrangements have been subjected are as yet too recent to enable us to draw definite conclusions as to the efficaciousness of the appliances.

We think, however, that we may make the following remarks relating to the ultimate general adoptions of these systems of route levers :

1° The employees in charge of the operation of the ordinary central apparatus of a station do not need to go through an apprenticeship so complicated or so difficult, provided that they are men of average intelligence *acquainted with the reyular traffic* in the zone to be operated on. It is this knowledge of the traffic which is indispensable and which must be obtained before a man can be trusted to learn the handling of the apparatus.

It would appear that some of the French engineers have been guided by the idea of being able to use anyone as signalman in case of a strike. But a man who was not thoroughly familiar with the traffic of the station could not effect any manœuvres other than the most simple ones, and those only provided that the electricians have not done any rattening. If the latter can be depended upon, they can always take the place of the signalmen. If they cannot be depended upon, the apparatus will be paralysed.

2° The working of the appliances at a station, no matter what system is employed for operating them, is inevitably subject either to disarrangement or to minor trouble requiring attention. These troubles are particularly due to the conditions under which many of the appliances on the track have to work; in particular, vibration due to the passing trains, dust from the ballast, the relative movement of different portions of the track, bad weather, etc. Periodic inspection is rendered necessary more frequently the more strict the conditions required for safety; it follows that it is frequently necessary to

(1) " Note on the double application of the M. D. M. automatic route-combiner to the hydraulic operating gear and to the interlocking of the points and signals at the Landy signals cabins, near Paris, by the French Northern Railway ", by A. Moutier. (*Bulletin of the Railway Congress*, Nos. 8-9, July-August, 1910, p. 3311.)

operate a track appliance singly for purposes of maintenance, and this can be done much more easily when the appliances are operated singly than when they are operated by route levers.

3° The economy of time which would appear to result from the making of a route in the route lever system, as compared with a system using individual levers, these levers being operated in a single stage, is an illusion. In fact, this time includes in both cases :

a) The time necessary for operating the points — which in both cases takes place in parallel — and for sending the indicator current which frees the operating gear of the signal;

b) The time necessary for operating the signal to set it to line clear.

It has been found by numerous trials which we have made, particularly at the Brussels Northern station, that the complete making of the most complicated routes never takes more than eight seconds, comprising :

Four seconds for operating the points and the auxiliary route levers;

Two seconds for setting the signal at the end of the route to line clear, which must be performed before the starting signal moves, and

Two seconds for setting the starting signal to line clear.

At the Valenciennes station, some routes require as much as thirty seconds for their completion.

4° So far as economy in the staff for operating the central apparatus is concerned, we think that this depends more on the quantity of traffic to be dealt with than on the dimensions of the apparatus to be handled. It is to be noted, in fact, that in fluid-operated cabins, the signalmen become just as tired as in the others although there is no muscular force to be exerted; this must therefore result from the mental effort which they have to exert to ensure the necessary sequence of operations.

5° Finally, in regard to the maintenance of the appliances, we think also that no economy results from the use of this or that system of operating levers; these systems only differ in the arrangement of the central apparatus, which should be under the best conditions for maintenance; we shall return, moreover, later, to the important question of cost of maintenance of fluid operated cabins.

We think that we may conclude that, in spite of the ingenuity which has been devised with a view to substituting route operation for single lever working, the advantages of the latter system are such that owing to the conditions of the problem to be solved, they will finally prevail. It is essential, moreover, that individual operation should be arranged so as to reduce to the minimum the number of operations to be made by the signalman and so as to enable them to be made as rapidly as possible. Consequently it is necessary that the apparatus should be operated in a single stage and that the indication in the cabin of the position of the appliances on the track should be effected electrically.

Besides this, we must remark that even the idea of appealing to the reasoning faculty, rather than to the memory of the

signalman for the formation of a route, is not rational.

It is a well known fact that if the operations are to be performed with great rapidity it is only by the reflex actions and not by the brain effort of the signalman that this result can be obtained. Thought should only be involved in those cases where the operations require initiative.

Failures. — As we said at the commencement of this Report, the brief replies we received to our list of questions, arrived so late that it was impossible for us to obtain supplementary details. It follows, consequently, from these replies, that the troubles which have been found in fluid-operated installations for working points and signals are few in number and not of serious importance.

In the hydraulically and pneumatically operated cabins, leakages have been the most frequent source of trouble, and have occurred especially at the joints of the pipes and at the packing of the pistons. In the electrically operated cabins, failures or troubles are due to faulty contacts, slacking of terminals, damage to cables, blowing of fuses owing to excessive resistance to movement, failure of indication due to the presence of foreign matter in the points, or to shifting of the track, etc.

We now come to a similar conclusion to that of our distinguished colleague, Dr. Ulbricht: it is that the greater number of troubles are due not to the use of electricity, but to disorganization of the track and of the points, of which the electrical appliances give a valuable indication. In those stations in which these have been introduced in Belgium, it has been found necessary to improve the condition in which the track is maintained, and derailments of locomotives have been entirely prevented. If it is desired to make a comparison with the ordinary mechanically operated installations, the fact must not be lost sight of that in the latter those troubles which the permanent way staff are accustomed to put right themselves, are not considered as failures, for example, the breakage of a transmission wire, a wire slipping off the compensating pulley, jamming of a lever, etc.

First Cost. — The first cost varies greatly between different installations, and is evidently dependent on the conditions required for the working of the traffic. Consequently, it is not possible to make a comparison between the various replies which we have received on this head, except where they relate to similar installations in respect to the signalling arrangements, the mean distance at which the points are operated, etc.

Dealing only with the Belgian installations, these give extremely complete arrangements for ensuring safety. All operations of moving trains are made to signal. The stop signals are always supplemented by distant signals. All routes are cleared automatically by the trains. At Brussels Northern station, all the tracks are insulated. The signals return automatically to danger behind the trains, etc.

We may mention that from the information received, the cost of installations operated hydraulically varies, in France from 2,217 to 2,500 francs (from £88.14*s.* to £100) per lever, and in Italy from 1,800 to 2,000 francs (from £72 to £80); that of an electro-pneumatic installation in Eng-

land varies from 2,075 to 3,500 francs (from £83 to £140) per lever.

In the installation at the St. Jean station, Bordeaux, on the Bleynie-Ducousso route system, the cost amounts to 2,250 francs (£90) per route lever, but the mains will require to be replaced by lead-covered cable, which will considerably increase the cost of the installation.

The installation of the two cabins at Villeneuve St. Georges on the Paris-Lyons-Mediterranean Railway, has required an expenditure of 770,000 francs (£30,800) for operating 45 sets of points and 62 signals; this amounts to 7,200 francs (£288) per appliance operated.

Finally, the last installation on the Siemens and Halske system, now being laid down at Alost in Belgium, will only cost 408,000 francs (£16,320) for 60 sets of points and 135 signals (single arms, track number arms and shunting arms), which amounts to about 2,100 francs (£84) per appliance operated, including the cost of the semaphores and of the plant for generating the current.

No conclusion can be drawn from figures which vary so much; they do not give more information than those which are quoted by our colleague Mr. Dufour at the end of section A of his report. However, we think it as well to go into some detail on the subject of the cost of the signalling arrangements now being laid down at the Alost station, in order to enable us to understand the advantages in economy of power-operated installations in comparison with the hand operation of points and signals at a large station.

This station, which comprises eight passenger tracks and a locomotive siding, is situated on the fast traffic line from Brussels Northern station to Ghent; moreover, two single tracks and one double track run into this station. In addition, at one end the station is connected to the Alost East Goods station, and at the other end to a group of sidings for coaching stock.

The operation of all these signals and points, which cover a length of about 1,200 metres (1,310 yards), is concentrated in a single cabin crossing the tracks, situated at the centre of the length of the passenger platforms, and fitted with an electric installation on the Siemens and Halske system.

To operate these appliances by hand would have required the construction of four cabins, comprising respectively 63, 110, 170 and 38 operating levers; these would have involved an expense of about 400,000 francs (£16,000), including the cost of construction of the cabins, notwithstanding the low first cost of Saxby appliances in Belgium.

The electrical installation has involved a total expenditure of 440,000 francs (£17,600), including the cost of the single cabin (1).

The extra expenditure in capital has therefore been only 40,000 fr. (£1,600), but it would have been saved after nineteen months' working. In fact, the cost of working, which amounts to about 48,000 francs (£1,920) per annum in the case of manual operation of the appliances, becomes reduced to about 22,000 fr. (£800) for electrically operated appliances. There is consequently an annual

(1) The figure 408,000 francs (£16,320) quoted supra does not include the cost of construction of the cabin itself.

saving of about 26,000 francs (£1,040) or 2,166 francs (£86.13*s.*) per month and 41,156 francs (£1,646.5*s.*) in nineteen months.

Cost of Working and Maintenance. — In general, the cost of working and maintenance comprise :

1° The wages of the employees responsible for operating the appliances;

2° The wages of the employees responsible for maintaining the appliances;

3° The supply of power necessary for operating the appliances;

4° The amount allowed for depreciation and for material required for maintenance.

We should note that as a general rule the greater number of railway companies consider it necessary to employ a special man in regular attendance to look after the maintenance of the appliances at a station. It is considered necessary to have such a man in order that it may be possible to set right immediately any trouble which may occur. Moreover, it is essential that the appliances should always be maintained in perfect order, and in this respect installations using a power supply have, in our opinion, an undeniable advantage over installations operated by hand; this arises from the fact that they indicate, almost automatically, the performance of the work of maintenance. The employee whose duty it is to ensure this maintenance, is constantly on the alert, and under the necessity of carrying out his duties with scrupulous care.

The supplementary expenses caused by the necessity of the continuous employment of this specialist are largely compensated for by the certainty that the installation is always kept in perfect order. These expenses can easily be compensated for by economy in signalmen at a station of some importance; up to the present no advantage has been found in substituting fluid-operation for hand-operation in the case of stations of less importance.

The solution of this problem may however by sought by designers. It is only necessary to obtain an economical petrol motor and one capable of being easily maintained in working order.

So far as the signalmen are concerned, we may state that no difficulty has been found in respect to filling their ranks, nor in their apprenticeship : in most cases it has merely been necessary to select the more intelligent of the employees provided they were conversant with the traffic of the station which they had to work.

An apprenticeship of from two to four weeks according to the magnitude of the installation has been found amply sufficient to familiarise them with the operation of the appliances, since this is generally much more simple than that of mechanically operated appliances.

In England, the contractors have gerally been required to construct the operating levers of a form similar to those of the Saxby levers. The handles usually adopted in France and in Belgium appear more suitable to the end in view, and have given rise to no difficulty in respect to the apprenticeship of the staff.

Current Supply Installations. — In the case of hydraulic installations, accumulators fed by motor driven pumps are generally employed; in the case of compressed supply, air compressors are used; and in the case of electric supply, accumulators of the Planté type are the power used.

The storage varies according to the requirements of the case, but it is generally only small in those installations which do not use electricity as a motive power. In this case, provision is generally made against possibility of failure of the current supply plant by installing a duplicate plant. The electro-pneumatic system, moreover, allows of the use of an ordinary locomotive fitted with a compressed air brake in case of failure of the compressor.

The capacity of electric accumulators is generally so calculated as to allow for working the installation during two or three days without re-charging. This is a very valuable feature in our opinion, and one which greatly favours the introduction of electric installations.

SECTION *B*.

Precautions taken for preventing the premature change of position of points before they have been completely cleared by the train, whether the points are taken facing or taken trailing.

Prior to the use of bogie carriages for traffic on railways, the distance from centre to centre of the wheels of passenger vehicles did not exceed 5·50 metres (18 ft. $^{9}/_{16}$ in.). The use of mechanical arrangements for preventing the operation of a set of points during the working of the traffic or while a train was on that portion of the track, then presented no practical difficulty. These arrangements generally consisted of a bar of iron or steel arranged in advance of the point tongue and operated by the locking bolt of the points or by the point lever itself, when this latter lever effected the locking of the points. The section of these bars was T-shaped, or they were made of angle-iron; during the travel of the lever, the bar was raised, and afterwards fell to its normal position; this movement was prevented by the flange of the tyres when a wheel was near to the point tongue.

The locking bar was arranged either on the inside or on the outside of the track. These arrangements, commonly adopted, are too well known to warrant our giving more time to them. As a general rule they are only applied to points on main tracks taken facing, either by through traffic, or by shunting trains when the latter operations are controlled by fixed signals.

With the advent of the bogie carriage, which took place but a few years since, it has been necessary to make use of locking arrangements which, in order to be effective, must have a length at least equal to the distance between the centres of the inside wheels of these vehicles. At the present time this has attained as much as 10 and even 12 metres (32 ft. 10 in. and even 39 ft. 4 in.). It will be readily understood that the construction and operation of mechanical locking-bars of such length is extremely difficult. On the other hand, the necessity for placing such arrangements in the middle of the track, appliances at newly constructed passenger

stations, comprising scissors crossings, and cross-overs consisting of a succession of double slip points, greatly increases the difficulty of the problem.

Whereas in England mechanical locking bars are still used up to 10 and 11 metres (32 ft. 10 in. and 36 ft. 1 in.) in length, those Continental countries to which our questions were addressed, and in particular, certain French companies, and the Belgian State Railways, have attempted to solve the questions by means of electrical arrangements dependent on the use of insulated rails. This method consists in electrically insulating a section of track of sufficient length, situated in advance of the point tongues, and connecting it to an electric circuit comprising a battery and an electro-magnet, the armature of which is made to act either directly or indirectly on the lever actuating the points, or on the lever of its point lock. When a pair of wheels is on the insulated rail length, it puts this rail length to earth through the opposite rail, and the electric circuit is so arranged that the corresponding operating lever is locked by the armature of the locking electro-magnet.

It has not been possible to apply this simple and neat solution of the problem in England up to the present time.

The report of the special Commission of the *Block Signal and train Control Board* of the United States (1) gives the following reasons against the adoption of track circuits in England :

1° The very small weight of a considerable portion of the goods rolling stock;

2° The small use made of the brakes on goods wagons allows of the formation of a sort of varnish on the tyres which is of too low conductivity to enable the pressure of the wheel on the rail to short-circuit the relay;

3° The use of Mansell wheels with a non-conducting centre of wood;

4° The use of cast-iron wheels with steel tyres making a poor electric contact between the tyre and the wheel centre;

5° The cant of the rails corresponding to the coning of the rolling surface of the wheels;

6° The existence of a sort of skin or varnish which is a poor conductor of electricity on the heads of rails which are in work.

These reasons, which relate equally to the use of electric treadles consisting of insulated rail lengths, are not found on the Continent.

Several French companies adopt generally, in the case of points taken facing, the use of insulated rails for securing the points during the time of passage of the trains. The interlocking appliances act upon the operating levers in each of their extreme positions. They are actuated by means of a current normally flowing and interrupted by means of a contact actuated by foot. The French Northern Railway and the Paris-Lyons-Mediterranean Railway, however, do not use these appliances. The French State Railway uses an electric treadle fitted on the outside of the rail. When this treadle is pressed down under the weight of the wheels of the train, an electric current is sent to a relay placed in the signal cabin, and the electric

(1) " First annual report of the Block Signal and Train Control Board to the Interstate Commerce Commission ", *Bulletin of the Railway Congress*, Number of June, 1909, p. 483.

current which allows the operating lever to be unlocked, is interrupted.

In Italy, electric treadles are also not used, although the maximum distance between the wheel centres amounts to 11·319 metres (37 ft. 9 $^1/_2$ in.).

The Belgian State Railways generally employ electric treadles 15 metres (49 ft. 3 in.) in length fitted to points which are taken facing. We have given all particulars relating to these arrangements, in a note which appeared in the *Bulletin du Congrès des chemins de fer*, March 1910.

We have there shown that the only obstacle in the way of the general adoption of the new arrangement — the difficulty of insulating the points themselves — has been overcome in Belgium in the most complete manner.

A second method of locking the points, during the time a train is running over them, consists in interlocking them by means of appliances actuated by the trains themselves. In general principle, these arrangements consist of an electric or mechanical rail contact acting on a lever in the cabin in such manner as to lock it until the moment when it is touched by the wheels of the train; when this lever is thrown over, it itself locks the points of the corresponding route in the position which they should occupy. It would evidently be possible to use the signal lever itself for the same purpose, but this arrangement would have the serious disadvantage that it would prevent the setting back again to danger of the signal once it had been set to line clear and before the train had run over the complete route made. This has resulted in arranging the interlocking on a special lever and involves the use of auxiliary route levers.

In some cases, for example in the Saxby installations, a locking lever or even a point lever may be utilized for this purpose. Arrangements of this kind are still but little used except in Belgium, where it is required that every route more than 200 metres (218 yards) in length, not fitted with a signal at the end of the route, must be fitted with a treadle at the end of the route. This treadle consists of a rail contact, generally of the Siemens (mercury) type, used, in conjunction with an insulated rail, in such manner that the route is only cleared when it has been disengaged by the last wheels of the train. The circuit (fig. 49) comprises a battery of from 4 to 6 volts, a switch *c* operated by the route lever, the relay *r* coupled to the treadle P by the wire 1, and to the insulated rail by the wire 2; the circuit of the interlocking electro-magnet which is connected on the one side to the earth, and on the other side to the insulated rail by the wire 3; the wires 2 and 3 are normally disconnected by the switches *i* and i_1 operated by the armature of the relay *r*.

When the first pair of wheels of the train runs over the treadle P, a current excites the relay *r* which attract its armature and closes the switches *i* and i_1; so long as a pair of wheels occupies the insulated rail RI, the relay current flows through the wire 2, the insulated rail, the axle and earth, and the interlocking electro-magnet is short-circuited forming part of the circuit : earth, the electro-magnet *e*, the wire 3, the axle, earth.

When the last pair of wheels of the train has left the insulated rail, the current from the battery passes through the relay *r*, the wire 2, the insulated rail, the wire 3, the electro-magnet *e* and to earth:

the electro-magnet *e* is excited and, attracting its armature, frees the route lever.

This very complete and positive arrangement works perfectly. Except in the case of very important installations where numerous shunting operations have to be performed, it has enabled the use of locking treadles to be completely dispensed with. It is, therefore, very economical.

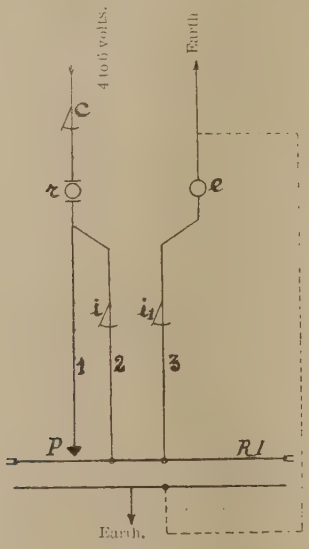

Fig. 49.

We think it is essential that arrangements should be fitted at the ends of routes, in all important installations consisting of long routes protected by a single signal, and particularly in those in which the points are fluid-operated. In these installations, in which no physical force is required for operating, the signalmen have a general tendency to throw back the signals to stop too quickly with a view to accelerating the traffic; they thus throw out of gear those interlocking arrangements which lock the point levers, so that these can be again operated before they have been run over by the train for which the route was made. In fluid-operated cabins particularly, where the operation of the points always takes two or three seconds at least, the train could enter the points while these were in motion, which would inevitably result in derailment. It is therefore essential to provide means for preventing this possible cause of accident.

SECTION C.

The use of a graphical method for facilitating the investigation of means of increasing the traffic on tracks serving passenger platforms, and the most important modifications required, affecting the tracks.

It follows from the particulars which have been supplied to us by those companies to whom we have sent the list of questions, that it is not customary to employ graphical methods for facilitating investigation of the best means of utilising the tracks serving passenger platforms.

Some companies occasionally use graphical methods on a time base for this purpose; these diagrams comprise as many horizontal lines as there are platform tracks, and are crossed by vertical lines corresponding to the twenty-four hours in the day, with intermediate divisions for every five minutes' interval. But this elementary method does not enable one to ascertain the possibility of effecting any particular movement of the stock at a particular moment in the day, without interfering with other traffic movements occurring at the same time; nor does it enable one to determine with certainty that a suggested time table is, or is not, workable with the arrangements existing in the station.

We have shown in the *Bulletin of the Railway Congress* (1) the graphical method, the adoption of which we suggested to the Belgian State Railway, applied by them to their large stations. This method which is at the same time very comprehensive and very simple, has been of great use in investigating the rational utilization of the passenger platform tracks, particularly at Antwerp Central and Brussels Northern stations. At the latter station, it has greatly contributed to the success of the final track arrangement brought into operation in 1907; it enabled this to be effected in a few hours at night, without causing any difficulty in the regularity of the train traffic. A note of this result was published in the *Bulletin of the Railway Congress* for September, 1907.

The Italian State Railways have also used the new Belgian graphical method for working out the arrangement of the large passenger station at Milan and have been extremely satisfied with the method.

CONCLUSIONS.

The reporters on question X have all drawn their conclusions independently of the work of their colleagues. Their schemes, therefore, only apply to those countries over which their investigations extended.

We have endeavoured to show, in the scheme which we are submitting, a general summary acceptable for all countries,

(1) « Note on diagrams used on the Belgian State Railway to facilitate the determination of the best utilization of platform lines at passenger stations », by L. Weissenbruch and J. Verdeyen (*Bulletin of the Railway Congress* of September, 1908, p. 933).

instead of one applicable alone to Britain, France, Italy and Belgium.

SECTION A.

The use of the fluid-operated central apparatus, principally for large stations, has made rapid progress during the last ten years. Such apparatus has the advantage of allowing of greater concentration, and, consequently, greater safety and greater rapidity of operation, while at the same time it renders more easy the work of the employees. It is also possible to obtain greater safety in working the traffic by arranging for the clearing of the routes by the train itself, by indicating the true position of the points, by obtaining the return to normal or stop position of signals after the train has passed (or in case of any disturbance in the route run over), etc.

The methods of power supply most usually employed, are on the one hand, electric current, and on the other hand, compressed air with electric indicating gear.

In the United States of America, where the latter system first came into most general use, electricity has taken the lead in latter years, and it is probable that it will continue to keep the lead over its competitors for the following reasons :

1° This system is more easy of adaptation and use;

2° The losses due to storage and in the distribution are very small;

3° The distribution and utilization of electric power are independant of variations of temperature or of severe extreme temperatures.

A similar tendency has been found in Europe.

In the case of isolated appliances, carbonic acid gas has been used with success.

In large stations to which an electrician is permanently attached, the concentration has led to a reduction in the number of signalmen. By this means, it has been possible to recoup the expenditure in capital while at the same time greater safety has been obtained than that which was formerly given by the old mechanical installations.

In France, trials are in progress with a view to operating all the points of a route by means of a single lever. The end in view is that of rendering more easy the apprenticeship of the signalmen.

In Germany and in Belgium, attempts to operate points simultaneously, other than those usually worked in combination for a cross-over, have been given up. In those countries, it is thought that the apprenticeship of the signalmen can always be effected quickly if they are familiar with the traffic at the station and that apprenticeship in quite useless unless they are familiar with the traffic.

Up to the present, the central electric installations have been operated by continuous current. Single phase alternating current and three-phase current have also been tried. Up to the present the following difficulties have been met with : difficulties of insulation, increased cost of the motor and of the electro-magnets, noise made by the motors when stopped, risk to the staff, and the impossibility of dispensing with accumulator storage.

Section *B*.

1° Mechanical and electrical appliances are in use for locking the points during the period while they are being run over by the trains. These arrangements, which should have a length at least equal to that of the greatest distance between the wheel centres of vehicles in use on the railway system, are not generally applied except in the case of points taken facing.

There is a tendency on the continent to gradually substitute electric treadles for mechanical treadles.

2° Electric treadles are generally worked by means of a normally flowing current interrupted by means of a foot-operated economiser switch; by this means the difficulty of insulation of the points can be easily overcome.

3° The arrangements at the end of a route, acting only after the last wheels have passed, enable all the points on a route to be interlocked up to the moment at which the train has entirely cleared the route. The use of these arrangements may be substituded for a series of locking bars at the points with economy.

Section *C*.

The use of a graphical method enabling the investigation of the best utilization of tracks serving passenger platforms may be of very great service, particularly in the case of modification of the track arrangement.

The method used by the Belgian State Railway in particular affords a general and complete solution of this problem.

SECTIONAL DISCUSSION

Meeting held on 9 July 1910 (morning).

MR. DIETLER, IN THE CHAIR.

The President. (In French.) — We now begin the discussion of question X. I call upon Mr. Verdeyen, reporter for Great Britain and colonies, Belgium, France and Italy.

Mr. Verdeyen, *reporter.* (In French.) — The question of the operation of switches includes three very distinct sections. I propose that the discussion should be divided and that we should not pass to littera *B* and littera *C* until the discussion of the first section, littera *A*, has been completed.

Mr. Dufour, *reporter.* (In French.) — In my opinion it is preferable that the reporters should first give summaries of their reports and that the three sections of the question should then be discussed separately.

Mr. Ulbricht, *reporter.* (In German.) — I agree with this proposal.

The President. (In French). — I call upon Mr. Dufour to give us his summary.

Mr. Dufour, *reporter.* (In French.) — I have been entrusted with drawing up a report on question X, as far as Holland is concerned.

The railway system of my country is rather a limited one, if compared with that of other countries with a similar density of population, owing to the numerous waterways which intersect it in all directions and which connect all the large towns and nearly all the villages.

The receipts which our railways obtain from passenger traffic are nearly the same as in adjoining countries; as regards goods traffic, they amount to as much per kilometre as those for passenger traffic but nevertheless, owing to the waterways, they are much less than in adjoining countries.

It is hence natural that the sums available for putting in safety appliances in Holland should not be very high, and we must limit ourselves to putting in such appliances successively on the important lines.

The railways in Holland are built partly by the State and partly by private companies, and they are operated by two companies which have about 1,500 and 1,800 kilometres (about 930 and 1,120 miles) of line respectively, and also by two other minor companies.

*

In order to make the large towns benefit by the competition of the two chief companies for the traffic to the ports and to the frontier, the State has imposed on some lines " rights of way ", by virtue of which complete trains of one company have the right of running over the lines operated by the other company.

As the Permanent Commission had appointed me as reporter for Holland only, and as I belong to the one company, I directly obtained from the other the information necessary and I drew up my report without having to send out a detailed list of questions.

My report contains to some extent a history of safety appliances in Holland, and the results of the experiments on which our signalling systems are based.

Littera *A*.

Only double-wire apparatus have been put in since 1883. The principles of construction adopted at that time have been retained since.

As a rule only semaphore signals are used, both for the main signals as well as for the distant signals. The latter have an arm cut square which when inclined at 45° downwards (or shows a green light at night) indicates slacking, while when inclined at 45° upwards (a white light at night) it gives " lines clear ".

On the lines of the Dutch State, the signals located between the outermost points are operated both for trains as well as for shunting operations. At new installations the general principle has been adopted of having a system of signals which extend to all the sections of the cabins, run over by trains or during shunting operations.

On the lines of the Dutch Railway this system has not been adopted, but special signals for shunting operations are used very extensively.

Fixed optical indicators, called " beacons ", are place by the track, at a distance of about 850 metres (930 yards) from the main signal, in order to warn the trains that they are approaching signals, if the weather is rather foggy.

The distance between the distant signals and the main signals, and that between the signals and the outermost points are not very great, for special precautions are taken in times of thick fog (telephonic and telegraphic messages, giving the position of the signals). These messages are sent to the previous cabin and there detonators are placed on the track. The distance between the two signals is only 450 metres (492 yards), and that between the main signals and the outermost points is 100 to 150 metres (109 to 164 yards).

The points and signals of small stations on single-track railways are centralized in a frame near the booking office, while two cabines are placed at the ends of double-track sections. Most of these cabines also attend to the level crossings.

Siemens & Halske block apparatus are used everywhere on the open line, and also for interlocking the signals placed at a distance from stations.

The frames used are of three types. The first type, very simple and very strong, having six locking bars, can be put up in the open air, but its construction does not make electric interlocking possible. It suffices for simple installations and seldom have used with hardly more than ten levers. In the case of other installations, Siemens & Halskelever apparatus or si-

milar apparatus are used, of the Dutch Railway Company's type.

The appliances for operating and locking the points have for some time been made so that the switch can be forced open from the trailing side; in the case of junctions and other parts of the track where shunting operations are not carried out, switches which can not be forced open are retained. Locking clamps are not used; the locking is effected by a thrust. The switches on the Dutch State Railway are only provided with signals exceptionally.

The semaphore signals consist of conical tubes made of steel plate; more recently Mannesmann steel tubes are used. The arm of distant signals is made of aluminium, so as to be lighter. In the lanterns, the nickel reflectors have been replaced by Fresnel glass lenses, which are supplied by an American firm. These lenses are cheaper and concentrate the light better. Where several signals are close together and when conditions are suitable, electric light is used.

On the return sheaves, rope is not used, but strong chains, attached to hooks soldered to the wires. In several cases return sheaves have been successfully replaced by wires laid in gas barrels curved to a large radius and filled with heavy tar oil.

Oscillating compensating gear, of a system not well known, is only used in rare cases. Most of the points taken from the facing side by fast trains are locked.

In order to make the position of a signal dependent on two or three cabins, very simple slot gear is frequently used, acting on the wire line.

Of late years, the Dutch railways have followed the example of neighbouring countries and have installed several centralized frames. These can only be used to a limited extent, as the zone of action of the cabins can hardly be more extended with power operation than with the double-wire system. The advantages found are as follows : the employees have to use less force and the apparatus are permanently controlled. It is a question whether these advantages will justify the greater cost.

Stahmer apparatusr, operated pneumatically and controlled electrically, and also purely electrical apparatus have been installed. The cabin apparatus are in both cases exactly the same. I think that the choice between these two systems is merely a matter of price or a matter of taste.

Both systems, as compared with each other, have sundry advantages and disadvantages.

Although I think that the cost of mainnance of power-operated installations is somewhat lower than that of hand-operated installations, the original cost is 30 to 50 per cent higher, not including the cost of the power supply.

Littera *B*.

The search for a simple and effective arrangement for preventing the premature shifting of points is one of the most important questions which have to be solved. A mechanical solution becomes more and more difficult because the distance between the axles of carriages is being increased, and the points at large stations are becoming more and more entangled.

The application of insulated rails has the disadvantage that wooden fishplates and electric connections have to be introduced into the steel track; moreover it has to be noted that good insulation can more easily be obtained where the lines are ballasted with good broken stone, than when muddy sand is used, as in Holland.

The mechanical system and the electric system are used in Holland. Mechanical treadles from 7 to 11 metres (from 23 to 36 feet) long and placed inside or outside the track are used with many switches. They are used generally in the case of the switches of small stations, operated from the platform; in the case of cabins where the work is performed by employees accustomed to operating switches, their use is limited; there electrical arrangements are sometimes adopted. We have now had in use for some time locking treadles in connection with switches, whose points rise from the bedplates instead of sliding on them. The raised point serves, over part of its length, as a prolongation of the treadle.

Nevertheless, I think that in the future electric devices will become used more and more.

Considering question X from the point of view of Holland, I have come to the following conclusions :

Littera *A*. — *Improved centralized installations for operating switches and signals. The use of water, of compressed air, of electricity, for working the transmissions. Electric interlocking. Route levers.*

The safety appliances in the Netherlands resemble in many respects the types of appliances in use in Germany and in Austria. The semaphore with arms takes the place of the disk signal used in those countries in the case of the distant signal.

For operating the points and the signals, double steel wire transmission has been exclusively in use for the last thirty years. These transmissions, which extend up to 550 metres (600 yards) for points, and up to 1,100 metres (1,200 yards) for signals, are only fitted with compensating gear under exceptional circumstances.

The distant signals are constructed in such a manner as to fall to danger in case of breakage of the wire. No arrangements have been adopted for locking the points in case of breakage of the wire.

The outermost points, worked at a distance of more than 250 metres (275 yards) are bolted. One of the two companies, the company for working the Netherlands State Railways, has extended the use of bolt-locks to the greater number of the important point-tongues, where these are taken facing by express trains. Many points are fitted with operating gear permitting them to be run through trailing when wrongly set.

The safety appliances, with the exception of the interlocking of the points, consist in general in that the signals cannot be set to " line clear " except with the mutual consent of two cabins. The use of signals with superposed arms showing the route is only adopted to a limited extent on the lines of the company for working the Netherlands State Railways. The drivers find a point signal slightly raised at the outer points of small stations for giving the direction at places where trains pass without stopping.

The Holland Railway Company, by adopting candelabra semaphores in several stations, has attempted to show the drivers the route which they are to take.

The company for working the Netherlands State Railways has adopted the use of the same signals for the trains and for shunting operations inside the stations, whereas the

signals of the Holland Railway Company apply only to trains in transit.

The company for working the Netherlands State Railways has adopted a system of line normally blocked on its main line, whereas the Holland Railway Company has adopted the block-system with line normally clear.

Centralised appliances for working points and signals depending on the use of compressed air or electricity as motive power, can be applied with success to large stations. These appliances have the advantage that they require no physical effort from the staff.

The degree of safety obtained with these appliances is greater than that obtained by hand-lever gear, because it is possible to have a permanent indication in the cabin of the position of the point-tongues and of the signals.

The Stahmer electro-pneumatic appliances have not shown the disadvantages which have often been attributed to them. It must be stated that the maintenance of tightness of the piping, and that condensation from moist air have not given rise to trouble.

The electro-pneumatic appliances can be applied without the addition of special mechanism to point-tongues consisting of flexible rail, in order to permit of the points being run through trailing when wrongly set.

The cost of electro-pneumatic installations and of entirely electrical installations is, exclusive of the cost of supply of energy, higher than that of the double-wire mechanical installations, although there are cases in which the costs differ little.

The cost of the electro-pneumatic installations is, for a small number of levers, much greater than that of the entirely electric installations. For installations of small size and of great extent it is necessary to work out the cost for each particular case.

The cost can be diminished by constructing the operating mechanism for the points and signals in large quantities of the same dimensions, by means of special machinery, and in a factory equipped for this purpose, as in the case of bicycles and sewing machines. It would be well to unite the appliances for operating and those for locking the point-tongues in a single appliance which could be fixed without difficulty to all points.

It is possible that in operating signals, the solenoid has some advantages. It has to be noted that even though the efficiency of the solenoid is less than that of the rotating motor, the question of efficiency is of no great importance, because the energy required for operating is only a small portion of the total energy required including that necessary for the indicator.

Littera *B.* — *Arrangements adopted to prevent switches taken from the facing or the trailing side from changing their position before the whole train has passed.*

It is possible to construct mechanical treadles (locking-bars) for separate points operated by the double-wire, which, when well maintained, can give satisfaction for a distance of 7 metres (23 feet) between consecutive wheel centres. In combining these treadles with points fitted with point-tongues which lift in their to and fro movement, the distance between consecutive wheel centres may attain 11 metres (36 feet).

If the distances at which the appliances are operated are not great, mechanical treadles 11 metres (36 feet) in length, can be operated with the points. These treadles have disadvantages in case the points are taken trailing when wrongly set.

For the numerous arrangements of points which are found in a large station, the use of separate treadles is almost impossible. It is necessary to have recourse to the bolting of routes. This bolting is unlocked after the passage of the train, either by the following cabin, or by a block-apparatus at the cabin itself, which can only be unblocked on condition that the train has passed a certain place.

These combinations usually apply only to

the regular trains; the shifting of a set of points under a train during shunting is not prevented.

It appears to be of importance that efficient forms of construction should be found, which may be applied to points whatever may be their situation, and which may apply to vehicles having successive axles at a great distance from each other, both for trains and for shunting operations and without causing delay where the traffic is congested.

Gentlemen, such are the summary and the conclusions of my report. As I stated at the start, this report is not the result of a detailed list of questions and my conclusions apply to a very limited field. They cannot be drawn up in such a categorical way as those which result from the answers of a large number of administrations, as in the case of the other reporters.

Although I am very ready to answer any questions I may be asked, I propose to you not to start discussing the conclusions I have read out. I think it would be better to discuss the conclusions in Mr. Ulbricht's paper which are drawn up more concisely, and which are the result of inquiries addressed to thirty administrations.

We could also discuss the conclusions certained in Messrs. Weissenbruch and Verdeyen's report.

The President. (In German.) — I request the second reporter, our vice-president, Mr. Ulbricht, to give us a concise summary of his report.

Mr. Ulbricht, *reporter*. (In German). — Owing to the vast extent of the territories covered by my report — there were twenty-seven administration located in the following countries : Germany, Luxemburg, Austria, Hungary, Rumania, Denmark, Bulgaria, Russia, Sweden, Switzerland, Servia, Turkey and Norway — I have thought it better, instead of going in for long details about construction, to try to give a general report of the state of the appliances we are considering. With this object in view, it seemed to me necessary to divide the first section of the question namely : littera *A* : *Improved centralized installations for operating switches and signals. The use of water, of compressed air, of electricity, for working the transmissions. Electric interlocking. Route levers*, into four parts; that is a classification which might also be adopted in the discussion.

I have divided this first section as follows : centralized hand-operated apparatus, that is to say, central frames by means of which apparatus at a distance are operated by manual power; then come central apparatus with power operation, in which the operation is carried out by means of some power; then comes a chapter on switches and signals generally; and finally there is a chapter about the electric interlocking of route levers.

My verbal summary can be very concise. It is impossible, in fact, to enter into the details of so comprehensive a subject, and you will allow me to refer you to my printed report. I shall be satisfied with drawing your attention to several points which are perhaps particularly suitable for discussion and may give rise to more ample commentary.

In the chapter relating to hand-operated apparatus, a particularly important question, considered in detail in my report, is that of knowing whether rodding or wire transmissions are to be preferred for operating signals.

Another question of great interest is the arrangement of cuttable locks, which I will not refer to further now. Then comes the question of the advisability of using the central frames for locking the switches, not for operating them, independently of the cases where the locking is simply added to the operation and serves as a control. The results of the inquiry differ as regards this system of locking at a distance from the switch. Some administrations adopt it on the large scale. But I have recognized that, taking it altogether, such locking of switches is only applied to a limited extent.

As regards the operation of signals, it is hardly necessary to say that double-wire transmission has assumed paramount importance. Allow me to read to you the final remarks made in my chapter dealing with hand-operated apparatus; they are as follows :

Important improvements in hand-operated apparatus are not in prospect for the moment. However, there is no doubt that further improvements will be made in the combination of electrical and mechanical devices, and it is to be expected that in this way many difficulties, which at present have arisen in the case of purely-mechanical treatment, will be overcome very satisfactorily. Thus the question of safety in the case of the fracture of a wire, is one which is very probably soluble by electrical methods. Then also it may be expected that the development of power operated installations will stimulate, in more than one direction, the design of hand-operated installations; for at present there is no question of replacing hand operation by power operation in the majority of cases, and attempts will be made to adapt part of the improvements in power operation also in the case of hand-operated installations.

The second chapter, dealing with central apparatus with power operation, is chiefly devoted to the comparison of the two systems of electrically-operated and electro-pneumatically-operated apparatus. You will find in my report the opinions of the different administrations relating to this subject; it shows that for the moment most of them are in favour of electric operation, which is already applied very extensively in the countries with which my report deals. You will see that the electrically operated systems of Siemens & Halske and of Jüdel & Co. are now represented in Germany by 243 installations, with 6,907 switch motors and 1,824 signal motors; in Austria, by 22 installations with 411 switch motors and 224 signal motors; in Denmark, by 8 installations with 77 switch motors and 7 signal motors; In Russia, by 3 installations with 40 switch motors and 9 signal motors.

On the other hand, in the same countries, there are 10 installations, with 1,135 levers, using compressed air, on the most usual system, namely the Westinghouse, represented by the firm Stahmer, of Georgsmarienhütte.

That is already a very notable extension of the use of apparatus with motors, and these figures show that this is a question of system to which great attention should be devoted.

What is of particular importance with these central apparatus with motors, is the question of knowing how much maintenance is required, whether many failures are to be expected, and what are the economic results.

As regards failures, I may mention that although as a rule a greater number of

failures has been observed with central apparatus with motors, it is as a rule easier to set them right than in the case of hand-operated apparatus. Here again I may be allowed to read the conclusion in my report, which runs as follows :

A saving in the staff, in the case of power operation is not everywhere effected, but as a rule there may probably be a saving of 20 to 33 per cent, as Alsace-Lorraine, Wurtemberg, Hungary and the Russian State Railway recognize. Prussia states that it depends on local conditions, whether and what saving in the staff can be effected.

Accordingly opinions also differ, as to what economical advantages there are. These are also affected by the occasionally high cost of maintenance, and by the interest charges on the considerable outlay required; the general experience up to date does not show that these are so marked as to form a strong argument in favour of the future extension of power operation. In Austria-Hungary however, economic advantages have resulted both as regards staff and as regards maintenance.

The question of the economic advantages is however in this case also not the only deciding one; the most important point at places with much traffic is to have such arrangement that the staff can, without being overworked, work the service smoothly, quickly and safely. All the administrations which have up to the present used power installations agree that they make it easier to work the service; this is a sufficiently-great advantage to make it certain that power installations will be used in future, in spite of sundry existing minor defects. Therefore those administrations also which have already tried power installations in cases of much traffic, are considering the further extension of power operation in the case of installations at large stations particularly as there is no doubt that progress will be made and such devices will become more and more reliable. Electric operation by motors in such cases receives much more attention than other systems. The administration of the Prussian State Railway, which alone has a considerable number of experimental electro-pneumatic installations in use, states that the comparative trials are not yet completed.

As regards switches and signals generally, the illuminating power necessary for the signal lanterns has been considered, and then the appliances for enabling the train to set the signal to " danger ", appliances which of late have been recognized to have many advantages and which have been adopted in many cases; finally also a particular evolution of central apparatus acting directly at the limits of their zone of influence on the cabs of drivers, I mean cab signals. I will read from my report a few remarks about this subject, for I think this is precisely a point which we might discuss :

Then also many inventors have for tens of years aimed at making a warning signal appear or sound in the locomotive cab when the train approaches a main signal standing at " danger ". But only a few of the devices proposed have proved at all promising. In the countries we are considering, matters in this respect have as yet only reached the experimental stage. The chief difficulty is that the electric-contact devices for conducting the current from the line to the locomotive (such as the Lartigue " crocodile " contacts) cannot be depended on to act satisfactorily under unfavourable climatic conditions, as extended trials made by the Saxon State Railway on a line in the Erzgebirge have shown; and that mechanical devises are not only very liable to destruction in consequence of the high speed of trains, but also exercise a bad influence on the reliable working of the distant signal, if connected with it. Nevertheless, several experiments have recently

been begun in Germany with the van Braam signalling system, in which a treadle on the line acting on a sensitive lever with a transmission to the cab, fitted to the locomotive, operates a powerful signal, records the operation and if required also applies the continuous brakes. The latter seems at first sight a desirable action from the point of view of safety; but weighty objections have been raised against it.

Attempts are also made to obtain a certain amount of protection against the overrunning of signals by having every case of over-running, even if it has not been attended by any detrimental consequences, recorded by an automatic recording gear; and the driver is afterwards held responsible.

Among the general applications of central apparatus, an important place is also occupied by communications within the limits of the zones of action of central apparatus in the case of sorting operations. Conjointly with this, we have described attempts made to introduce a system of automatic sorting, a system in which any communication within the zone is required less than in the usual practice. At the end of this chapter, I make the following remarks in my report :

Very good results have been given, in the case of a shunting service, in order to communicate between the top of the inclines and the switches at the corresponding sorting sidings, by loud-speaking telephones as well as by electric track indicators, which are constructed on the pattern of needle telegraphs. Track indicators which have incandescent lamps lighting up behind transparent number plates, have also been used with advantage.

Mechanical needle instruments with a wire transmission have also been used instead of the electrical instruments. In many cases however, for instance in Switzerland, the siding numbers are only written on the buffers of the descending wagons; in Bavaria, numbered plates are hung on the buffers.

Newer installations and arrangements are devised with the object of making it unnecessary to given individual indications in the case of each descending wagon as in accordance with American practice the order of sequence of the different sidings on to which the wagons are to run is laid down in advance in writing, so that the switches can be set in succession in accordance with this list. A further step in advance is the use of power installations to carry out the sorting operations required; in the system devised by Messrs. Siemens & Halske, a paper band, perforated to correspond to the list, regulates the sorting automatically.

No further improvements in connection with switching and signalling appliances are contemplated by the different administrations.

I will say but a few words about the electric interlocking of route levers. The report I submit makes a special mention of the kind of current to be used (direct current) and of how the interlocking is effected, either by rail contacts acted on by the train, or by the train manager at the station, by means of an electric current.

Finally I say a word, in my report, about group-blocking, used on different railways and in various forms; I will not refer to this now. This chapter concludes with the following remark :

In the cases in which sufficient experience is available, the electrical route-interlocking has without exception given favourable results. There is no expression of opinion in its disfavour even in cases of much traffic. Several administrations also speak in favour

of mechanical route-interlocking. It is however to be noted that Prussia does not intend to use mechanical interlocking in future. Electrical route-interlocking is also strongly recommended in the case of new installations; in some cases, attention is also drawn to the fact that under certain circumstances mechanical interlocking may be also advisable.

Such are the four chapters of littera *A* of question X.

Then comes littera *B*: *Measures employed for preventing the premature operation of switches.* Here we have in the first place to note the length found practical for these appliances.

As a rule it is 10 to 12 metres (32 ft. 10 in. to 39 ft. 4 in.), and attains 13·50 metres (44 ft. 3 $^1/_2$ in.) in Saxony and 16 metres (49 ft. 3 in.) in Wurtemberg. Then I have to mention the use of electric block apparatus, conjointly with insulated rails and rail contacts, which involved a detailed examination of insulated rails and of the construction of the insulating joint.

Finally you will find in my report a discussion about rail contacts, with special reference to the recent type of drop contacts. This chapter concludes as follows:

No particular difficulties in the service or in maintenance have arisen from the use of these safety appliances for preventing the premature operation of switches. The general opinion on the contrary is that they have a favourable influence on the carrying out of the service.

Finally the report mentions the graphic representation of the utilization of platform tracks. As regards this point, I have not obtained much information. Many administrations use such graphic representations, and that with satisfactory results. I may remark that such graphics apply not only for the utilization of platform tracks, but can also be used for other tracks and are particularly convenient when train time-tables are to be modified.

This is my final remark:

The graphic representations of the occupation of the track, mentioned above, are by no means limited to platform tracks; they are also frequently extended, in so far as they are used at all, to other entrance and departure tracks. This applies especially if we also include among them the marks appearing in in the case of electric unlocking appliances. With this extended meaning attached, it also applies in some cases to locomotives running light, while graphic representations proper, of the track, are not used in these cases and in the case of shunting operations.

The arrangements mentioned are stated to give good results both as regards the facilitation of the service and as regards safety. The use of graphic representations has proved especially valuable when special trains have to be intercalated.

In organizing the train service at a large station, as far as the point of view of safety is concerned, the importance of such graphic representations is small as compared with the further development of electrical checking devices and means of communication, which make it possible for the different apparatus to work separately and yet form one united whole from the point of view of safety.

I have not given you any conclusions proper; I preferred, at the end of my report, to enunciate forty-three propositions, forming a summary of the chief results. But I do not consider it impossible to take these propositions, or at least those which meet your approval, as basis of a resolution, declaring that the section agrees with this summary of the results of the

report. It will of course be for you to decide whether you will proceed in this way. But if so, I would now already remark that I have made a small addition to article 25, which I will mention when the different articles are discussed.

In conclusion I may add that one of the administrations concerned only sent me its answers a week ago; namely that of the Norwegian State Railway; hence it was impossible for me to utilize this information in my report. At the beginning of this meeting, I have just received a letter from the Swedish State Railway, giving supplementary information relating to question 16 in the list of questions; when the time has come, I will submit this to the section.

The President. (In German.) — As Mr. Carter is not present, I call upon Mr. Verdeyen.

Mr. Verdeyen, *reporter*. — Mr. Weissenbruch, whose duties as general secretary prevent him from being present at the beginning of this meeting, has asked me to make his apologies.

LITTERA A.

Gentlemen, in our report we have only considered installations for operating switches and signals by power transmission. It was in fact only starting from the time that the signalman had no longer to use the power of his arms, when what is called power signaling was instituted, that real improvements could be introduced into the operation of switches and signals.

Our report includes in the first place a summary description of all the operating systems in use in the different countries to which our inquiries extended.

The investigation has led to the following general considerations :

The operation of switches and signals *at a distance* is effected by means of water under pressure, compressed air and electricity. With water under pressure and compressed air, motors with pistons are used, the reciprocating movement of which can be transmitted direct to the switches or signals, while with electricity solenoids have for various reasons as a rule been given up, and motors are used and their rotation is converted into rectilinear movement by means of gearing, by spur wheels and racks. But this apparent advantage of water under pressure and of compressed air is largely counterbalanced by the disadvantages inherent in those two methods of transmitting power. These disadvantages are the leakage at the joints and at the packings of the pistons, the difficulties of replacing one motor by another in case of a break-down, or when the maintenance of these appliances has to be attended to; and as regards more especially water under pressure, the care required during winter to prevent freezing.

Our American colleague, Mr. Carter, moreover states that in his country, where are many applications of compressed air, electricity now offers the greatest advantages.

As regards the control of the track appliances, it is considered indispensable, in the case of power installations, to have a device in the cabin for showing the positions of the appliances which are at a distance. This control can be operated by means of compressed air, of water under pressure or of electricity. But compressed air and water under pressure have certain disadvantages, particularly as

regards the time required before the checking operation is completed. This in the case of compressed air may take as long as twenty seconds, and in that of water under pressure from ten to twelve seconds; in the case of electricity, on the contrary, the checking is instantaneous, and this method is also the cheapest. The *French Northern Railway Company* is trying a new system, known as the M. D. M. system, in which there is a hydraulic control which works relatively quickly.

An objection which might be raised against the electric control, is that wrong indications might be given if the wires became entangled or if the conductors became faulty. Hence it is necessary to establish the electric circuit in such a way that a wrong indication can never be given; and this is a point which certain designers sometimes seem to forget.

In this respect, the Siemens & Halske system and the Siemens Brothers system have the great advantage, as compared with all other systems in which an electric control is used, of entirely eliminating the risk of a wrong indication should the wires become crossed.

There are two kinds of electric control to be considered : the permanent control and the momentary control. The latter only acts at the moment the movement of the apparatus operated is completed and ceases immediately after the second stage of the movement of the lever has been carried out. As regards the permanent control, this starts acting and remains in action as long as the appliance at a distance is in a position corresponding to that of the lever operating it.

The first system accordingly has the disadvantage of making it necessary to divide the operation of the lever into two stages, so as only to release the mechanical interlocking after the actual indication that the operation is completed has been received.

On the Paris Ceinture line, where the Taylor system has been installed as an experiment, with its " absolute " system of control, the railway company has required the addition of a permanent control.

As regards the operation of signals, it has to be noted that both in France and in England, as a rule, the single-action system has been retained, the signal being returned to the " danger " position by gravity.

In Belgium, on the contrary, we have a system which enables us to move the signal in both directions. Moreover, between the signal and the operating apparatus, there is an electric device which with this double-acting system obtains a degree of safety similar to that obtained in the case of mechanical double-wire transmissions, the signals being automatically set to danger should a wire break.

As regards central apparatus, the systems used in the countries considered in our report generally include individual operating levers for operating the points and signals. In France, different railways have applied the systems known as " route-lever " systems, in which all the switches and signals of one route are operated by a single lever.

These appliances are comparatively new and we do not think that this practice is as yet well established.

In our report, we have examined these installations, more especially from the point of view of the time the signalmen

take to become acquainted with it, the staff and time saved, the ease of maintenance, etc.

These considerations show, in our opinion, that the system of individual operation is of equal value, if not preferable, from all the points of view, to the system of operation by means of route levers. We think that this point will attract the attention of the section during the discussion.

The failures which occur in the case of fluid-operated installations for working switches and signals are few in number and of minor importance.

In the hydraulically and pneumatically operated cabins, leakages have been the most frequent trouble, especially at the joints of the pipes and at the packings of the pistons. In the cabins operated electrically, there are failures of contacts, slacking of terminals, damage to cables, blowing of fuses, failure of indication due to the presence of foreign matter in the points, etc.

Now, as Mr. Ulbricht has remarked in his report, most of these failures are not due to the use of electricity, but to defects in the track and the switches, of which the electrical appliances give valuable indications

As regards first cost, this varies greatly with different installations, and it would be difficult to make any comparison.

In our report we have compared the Saxby installations such as they exist in Belgium, with the Siemens & Halske apparatus used at Alost.

The operation of all the signals and switches, which cover a length of about 1,200 metres (1,312 yards), is concentrated in a single cabin crossing the track, fitted with an electric installation on the Siemens & Halske system.

To operate these appliances by hand would have required the construction of four cabins and would have involved an expenditure of about 400,000 francs (£16,000). The electric installation has involved an expenditure of 440,000 francs (£17,600). The extra capital expenditure was hence only 40,000 francs (£1,600), but this will be saved after nineteen months of working. For the working expenses would have amounted to about 48,000 francs (£1,920) per year in the case of manual operation, while they became reduced to 22,000 francs (£880) in the case of electric operation. There is consequently an annual saving of 26,000 francs (£1,040) or 2,166 francs (£86.13 *s.*) per month ; and of 41,154 francs (£1,646.3 *s.*) in nineteen months.

The current-supply installations are generally accumulators fed by motor-driven pumps in the case of hydraulic installations; in the case of compressed air, air compressors are used; and in the case of electricity, accumulators of the Planté type.

Here again we find the advantage of electric accumulators in the fact that they can be arranged so as to allow for working the installation during two or three days without recharging.

Littera *B.*

The question of treadles has given rise to much trouble since bogie carriages have been started running on railways. Formerly the treadles or locking bars only had to be 5·50 to 6 metres (18 ft. $^1/_2$ in. to 19 ft. 8 in.) in length, while now the

length must to be 10 to 12 metres (32 ft. 10 in. to 39 ft. 4 in.); on the lines of the Belgian State Railway we have even adopted a length of 15 metres (49 ft. 3 in.), with an eye to the future.

The construction and the operation of mechanical treadles of such length are difficult and expensive. Accordingly, in most countries, mechanical treadles are generally being replaced by electric treadles.

There is a second method which makes it possible to keep the switch immovable during the passage of the trains; this consists in locking it by means of devices operated by the trains themselves. This electric or mechanical device is in this case placed on the track, and acts on a lever in the cabin, so as to make it immovable until it is moved by the wheels of the train; this lever in its thrown-over position locks the switches of the corresponding routes in the position which they should occupy.

This second method is yet but little used, except in Belgium, where it is prescribed that every route more than 200 metres (219 yards) in length, not fitted with a signal at the end of the route, must by fitted with a treadle at the end of the route.

Littera *C*.

The information supplied to us shows that until now graphical methods for facilitating investigation of the best means of utilizing the platform tracks of passenger stations are seldom used.

The Belgian State Railway has adopted a graphical method which consists, taking it altogether, in applying to the stations the graphical time-tables used for the trains.

This method has given goods results and the Italian State Railway, which has applied it at Milan station, has been very satisfied with it.

The following are the conclusions which we have the honour to propose to you, conjointly with our colleague Dr. Ulbricht :

Littera *A*. — The use of the fluid-operated central apparatus, principally for large stations, has made rapid progress during the last ten years. Such apparatus has the advantage of allowing of greater concentration, and, consequently, greater safety and greater rapidity of operation, while at the same time it renders more easy the work of the employees. It is also possible to obtain greater safety in working the traffic by arranging for the clearing of the routes by the train itself, by indicating the true position of the points, by obtaining the return to normal or stop position of signals after the train has passed (or in case of any disturbance in the route run over), etc.

The methods of power supply most usually employed, are on the one hand, electric current, and on the other hand, compressed air with electric indicating gear.

In the United States of America, where the latter system first came into most general use, electricity has taken the lead in latter years, and it is probable that it will continue to keep the lead over its competitors for the following reasons :

1° This system is more easy of adaptation and use;

2° The losses due to storage and in the distribution are very small;

3° The distribution and utilization of electric power are independent of variations of temperature or of severe extreme temperatures.

In Europe, electrically-operated installations are the most used form among power-operated installations.

In the case of isolated appliances, carbonic acid gas has been used.

In large stations to which an electrician is permanently attached, the concentration has led to a reduction in the number of signalmen. By this means, it has been possible to recoup the expenditure in capital while at the same time greater safety has been obtained than that which was formerly given by the old mechanical installations.

In France, trials are in progress with a view to operating all the points of a route by means of a single lever. The end in view is that of rendering more easy the apprenticeship of the signalmen.

In Germany and in Belgium, attempts to operate points simultaneously, other than those usually worked in combination for a cross-over, have been given up. In those countries, it is thought that the apprenticeship of the signalmen can always be effected quickly if they are familiar with the traffic at the station and that apprenticeship in quite useless unless they are familiar with the traffic.

Up to the present, the central electric installations have been opperated by continuous current. Single phase alternating current and three-phase current have also been tried. Up to the present the following difficulties have been met with : difficulties of insulation, increased cost of the motor and of the electro-magnets, noise made by the motors when stopped, risk to the staff, and the impossibility of dispensing with accumulator storage.

Littera *B*. — 1° Mechanical and electrical appliances are in use for locking the points during the period while they are being run over by the trains. These arrangements, which should have a length at least equal to that of the greatest distance between the wheel centres of vehicles in use on the railways system, are not generally applied except in the case of points taken facing.

There is a tendency on the continent to gradually substitute electric treadles for mechanical treadles;

2° Electric treadles are generally worked by means of a normally flowing current interrupted by means of a foot-operated economiser switch; by this means the difficulty of insulation of the points can be easily overcome;

3° The arrangements at the end of a route, acting only after the last wheels have passed, enable all the points on a route to be interlocked up to the moment at which the train has entirely cleared the route. The use of these arrangements may be substituted for a series of locking bars at the points with economy.

Littera *C*. — The use of a graphical method enabling the investigation of the best utilisation of tracks serving passenger platforms may be of very great service, particularly in the case of modification of the track arrangement.

The method used by the Belgian State Railway in particular affords a general and complete solution of this problem.

The President. (In German.) — Gentlemen, now that you have heard the reporters, I will open the general discussion. It has been proposed to adopt the same subdivision as in the wording of the question. The reporters have declared that they agree herewith.

I will accordingly read out the question again. Littera *A* runs as follows : " Improved centralized installations for operating switches and signals. The use of water, of compressed air, of electricity, for working the transmissions. Electric interlocking. Route levers."

Thus section A includes all that refers to central apparatus operated by hand, as also central apparatus generally.

As regards littera *B*, we then will have to consider : " Arrangements adopted to prevent switches taken from the facing or the trailing side from changing their position before the whole train has passed " and as regards littera *C*: " Use of diagrams to facilitate the consideration of the full utilization of tracks along passenger platforms and the modifications to be made, in cases of urgency, in the way these tracks are used."

It seems, to judge by the summaries of the reporters, that the conclusions drawn up by Messrs. Weissenbruch and Verdeyen correspond to the list of questions. As Mr. Verdeyen has stated, Mr. Ulbricht has agreed to these conclusions subject to some small modifications in thewording, so that it is reasonable, in my opinion, to take the conclusions of Messrs. Weissenbruck and Verdeyen as basis of the discussion. I have also thought that we might request the reporters to meet at the end of the discussion in order to draft joint conclusions. Of course, the discussion will show whether this idea should be carried out : in the first place we will have to see whether there are any marked differences of opinion.

What do you think of this general programme ?

Mr. Ulbricht. (In German.) — I agree unreservedly to the proposal that the conclusions of Messrs. Weissenbruch and Verdeyen should be taken as basis for the discussion ; I have come to an agreement with them ; nevertheless I would remark that the report of Messrs. Weissenbruch and Verdeyen deals above all with power-operated central apparatus and leaves hand-operated apparatus out of consideration. The question really related to central apparatus generally, and improvements made in them, consequently also to hand-operated apparatus ; accordingly I included the latter in my report. I therefore think that if the discussion is based on the conclusions submitted by Messrs. Weissenbruch and Verdeyen, it will be necessary to devote separate attention to the improvement of hand-operated central apparatus. As regards that part of the discussion, the proposals made at the end of my report might serve as convenient basis.

It will accordingly content myself, for the moment, with recording that our programme will not be complete, as regards section A, if we adopt Messrs. Weissenbruch and Verdeyen's conclusions, because they do not include the improvements in hand-operated apparatus. Of course, the order in which the different sections are discussed is a matter of indifference.

The President. (In German.) — I think that Mr. Ulbricht's remarks should be taken into consideration, although I am informed that the wording of the question does not, strictly speaking, include central apparatus operated by hand. It is true, on the other hand, that the question has been enunciated in a general form and we can hence very well include hand apparatus within it. The best way of meeting Mr. Ulbricht's view would no doubt be first to discuss central apparatus operated by hand, and then go on to power-operated apparatus.

Mr. Verdeyen. (In French.) — Mr. Ulbricht then proposes to take as basis the conclusions which I have the honour to

submit to you. But he also asks that the question of hand-operated apparatus should be discussed.

I think I must observe that neither Mr. Carter's report, nor ours, consider these installations.

Hence I would like to see — and such is my proposal — that the question of hand-operated apparatus should be inserted among the agenda for the next session.

The President. (In German.) — I think it would be better if we discussed the whole question thoroughly. It does not seem, moreover, that there is any difference of opinion. In the first place we might discuss the question as a whole, but without going too far into details. As hand-operated apparatus represent the type most used up till now, I would not exclude them from the discussion, but would repeat the proposal I have just made as regards the order to adopt. We shall then see whether or no we have to make any additions to the conclusions. I will accordingly ask you to decide, as regards improved installations, as to the chief improvements made in central apparatus operated by hand.

In this connection, Mr. Ulbricht has already observed that the question arises whether rodding or wire is best for the transmissions. That question seems to be one of a very practical order and which has no doubt given rise to many different observations, so that it would be of interest to all administrations to know the results obtained in practice.

Mr. Ulbricht. (In German.) — As this question is only considered in my report, we could take as basis for the discussion the first fourteen conclusions in my report (1). The more important questions in connection with central apparatus operated by hand are there given. One could perhaps pass from one point to the next and say whether the summary given in that part of my report meets with your approval. It is a simple proposition which I am making.

The President. (In German.) — I will accordingly propose that a general opinion should be expressed about what Mr. Ulbricht says in that chapter of his report, which deals with hand-operated apparatus. The reporter himself has nothing to add.

Mr. Rank, Austrian State Railway. (In German.) — It is said in clause 9 of the conclusions of the report :

> The intercalation of control locks in the wire transmissions of signals is not quite without influence on the certainty of the operation; nevertheless it is frequently used in order to simplify the installations.

Thus it is recorded that such control locks exist. Now from the point of view of safety, there is no reason for congratulating oneself on this. This always involves a risk for the working of the signal, as the lock prevents the transmission wire from returning to its normal position. I think it is advisable to add to clause 9 a supplementary sentence to this effect; it might for instance be said that this device is only rational if the lock does not interfere with the return, should a wire break.

Mr. Ulbricht. (In German.)—That interpretation is perfectly exact. In any case,

(1) See page 62 of the report, and also *Bulletin of the Railway Congress*, January 1910, p. 354.

the point is dealt with at greater length in the body of the report. The wording of clause 9 is merely intended to express the facts as shortly as possible. I think that I drew sufficient attention to the question by the statement that devices of this kind, however well designed, are not without influence on the certainty of the operation. No doubt, among these devices, there are some which act very differently. Some of them are constructed so that they affect the operation very appreciably; but on the other hand, improved types of control locks have lately been invented which but little affect the certainty of the operation. Actually I am not in favour of such intercalations which always have some disadvantages, but I know that some very careful administrations use such control locks and intend to continue to use them in future; accordingly I have worded the clause so that the intentions of these administrations should not be in absolute contradiction with the practice which we shall perhaps approve here.

The President. (In German.) — What would be the wording of the addition? And does Mr. Ulbricht approve?

Mr. Ulbricht. (In German.) — In my opinion, no addition is necessary; but if it is really desired, I will not oppose it. We might say : " Particular care should be taken, however, that the intercalation of a control lock should not form any obstacle to the operation of the wire transmission ", or " that certainty of the operation of the wire transmission should not be reduced by the control locks."

Mr. Rank. (In German). — It would suffice to say that the return to normal position must not be impeded by the control locks.

The President. (In German.) — I would ask Mr. Rank, and generally speaking all delegates who wish to propose amendments to any conclusions, to reduce them to writing. The bureau cannot undertake the work of drafting.

Mr. Dufour, *reporter.* (In French.) — It is not necessary to introduce Mr. Rank's amendment. What is stated in the conclusion is the practice everywhere.

Mr. Jullien, Orleans Railway. (In French.) — I should like to make some general remarks.

Mr. Ulbricht's conclusions do not apply to all countries. They more reflect what is the practice in Germany than what is done elsewhere. Thus after speaking of the modern evolution of operating switches from a distance, it is stated :

> The operation of switches by means of rod transmissions is preferred to a smaller extent, in some cases only under special local conditions; such transmissions are less liable to fracture, but any fracture is not controlled automatically as easily as in the case of double-wire transmissions.

Now in France and in England, the operation of switches by rodding is the usual practice and only in exceptional cases is operation by wire adopted.

This conclusion can accordingly not stand.

If the statement is true for Germany it is not so for England and still less for France.

Clause 5 of the same conclusion runs :

> The most usual way of securing the blade is by a thrust obtained from a special point of

support, but switch locks in which the blade and stock rail are clamped together are now used more extensively.

That is true neither for England nor for France. I even think that such a thrust would be difficult with us; as regards clamping, this assumes the switches to be operated in a particular way.

A little further on, I see :

The locking of switches is only applied to a limited extent, apart from the control locking of switches which are far off.

On the Orleans Railway, this operation is often effected by locking from a distance.

The conclusions also include :

Double-wire transmissions are exclusively used for the operation of signals at a distance.

Now on many of the French railway systems, single-wire transmissions are used.

Finally I have a remark to make about clause 12, which runs as follows :

The use of ball bearings and roller bearings in switch and particularly in signal installations has proved advantageous; but as yet they are used only to a limited extent.

On the system of the Orleans Railway, ball bearings are used exclusively.

Mr. Ulbricht. (In German.) I leave it to you to decide whether or not to adopt as definite conclusions the proposals I submitted to you in my summary. As I have already told you, I did not draw them up from this point of view; they represent on the contrary the results of my inquiries addressed to Bulgaria, Denmark, Germany, Luxemburg, Norway, Austria, Hungary, Rumania, Russia, Sweden, Switzerland, Servia and Turkey. I of course did not mean to assert that what I said applied also to France and to England. As I have already remarked, these proposals are not conclusions strictly speaking, but must only be considered as a summary of what exists in the States which I have just enumerated and as applying to them only, but not as conclusions applying equally to all the countries represented here; that is a point which I wish to emphasize once more. In my opinion, the best practical solution would be simply to come to an agreement whether the proposals contained in those paragraphs express, as regards the countries in question, existing conditions with sufficient accuracy to be considered in that sense as conclusions. I do not know whether this would be in accordance with the usual practice of the Congress; in any case, the state of affairs seems to me the same as in the case of the report of my colleague which deals with the Dutch railways. In that case also it could not be said, that the conclusions given are of general application.

Mr. Verdeyen. (In French.) — In the interests of the discussion, it would be advisable to postpone the question of hand-operated apparatus to a future session, all the more so as all the information we have before us today is that relating to Holland and to that part of Europe to which Mr. Ulbricht's inquiries were addressed.

Mr. Maison, ministry of public works, France. (In French.) — It seems that in the first part: Central apparatus with hand operation, it is not a question of mechanical apparatus, but of apparatus operated by hand.

I find the following among Mr. Ulbricht's conclusions :

In the case of important switches taken from the facing side, whether the transmission be by rod or by double wire, it is in many cases considered necessary to have control locking in addition to the locking of the cabin apparatus.

That means to say that in many cases one must not be satisfied to lock the switches, but must also have controlling gear.

That conclusion appears to me to require an addition.

In France, facing switches over which trains may have to run at speed are always locked and generally fitted with an electric control. But this electric control only serves to give information to the signalman; it informs him whether the points are properly home, one side or the other, or whether on the contrary they are not home. That is not enough to ensure safety. It is not impossible, even in the case of rigid rod transmissions, for a switch lever to be pulled over in the signal cabin without the switch having moved in a corresponding way. There is then a want of agreement between the position of the operating lever and the position of the switch, and this want of agreement, which is not shown by the switch control, may cause an accident. Hence the present tendency in France is not to be satisfied with switch controls, but to work out devices making it possible to obtain, independently of the interlocking of the operating lever, a perfect agreement between the actual position of the facing points and that of the signals.

Hence it appears that clause 4 should be supplemented, as regards France, by the phrase : " The tendency is even to fit the apparatus with devices for ensuring a perfect agreement between the position of the switches and that of the signals, independently of the interlocking between the levers ".

Mr. Ulbricht. (In German.) — Perhaps one would wish to say that there is not everywhere control locking when the switch is in its normal position. In the countries considered in my report, nearly all switch operations are arranged so that the last part of the travel produces locking, and hence forms control locking. It is only in the case of very distant and particularly important switches that special control locking is used. That is the reason why it is only in certain cases that I have specified special control locking, with an independent wire transmission.

Mr. Jullien. (In French.) — The point just raised by Mr. Maison is interesting, but it seems to me to be difficult to embody it in a conclusion. It has in fact not been investigated and the reporters for the French-speaking countries do not even mention it in their work.

That being so, it would be preferable to drop the discussion of hand-operated apparatus and to postpone the question to another session.

The President. (In German.) — Several members accordingly desire that the question of hand-operated apparatus should be postponed to the next session. (*Hear, hear !*)

As there is no opposition, that shall be so.

Mr. Ulbricht. (In German.) — I must perform a duty which I have already

mentioned. Although this chapter is now to be left out of consideration, I must mention that the administration of the Swedish State Railway has asked me to state that its answer to question 16 of the list of questions is not given quite correctly; that it must be corrected in this sense that the operation can take place, not in the middle position of the lever but in each of the end positions, with an action on the central apparatus similar to that produced when a switch is burst open. (See appendix I.)

The President. (In French.) — We now pass to littera *A* of the conclusions in Messrs. Weissenbruch and Verdeyen's report.

I call upon Mr. Maas-Geesteranus.

Mr. Maas-Geesteranus, Dutch Railway Company. (In German.) — Gentlemen, I wish to remark that if we adopt Messrs. Weissenbruch and Verdeyen's conclusions, we at the same time accept those of Mr. Carter, and I will add that on our railways in Holland, we also have several electric and electro-pneumatic installations in use. The results obtained with the electro-pneumatic service are so favourable that we have decided to use it in the case of new installations. In fact, in our opinion, the maintenance is much simpler and cheaper, and failures are much rarer than with the electric systems. Among the disadvantages, there has been mentioned in the first place, leakage of air. I recognize this disadvantage; it is true that the consumption of energy is greater with a pneumatic installation than with an electric one. The reason is that in the former case the electric energy is in the first place converted into pneumatic energy. The leakages in the compressed-air tubes are, in my opinion, quite unimportant; but this is not so as regards leakages in the cylinders. On the other hand, failures are much rarer with pneumatic installations than with purely electric installations. The influence of the temperature has been mentioned; I may tell you that we have noticed nothing of the kind, It rather seems to me that in winter, for instance, there are many more failures with electric installations than with pneumatic installations, because in the latter case the amount of power available is greater.

I may also mention that on main lines we hardly use anything except switches with flexible switchblades, and it is above all the combination of electric motors with cuttable switchlocks and flexible switchblades which has given rise to failures. This has led us to give up cuttable locks, and in ordering new installations we now ask for non-cuttable locks, cuttable locks having caused too many failures.

I therefore think that we cannot yet say definitely, as regards Europe, whether pneumatic installations or purely electric installations are to be preferred. Moreover, the two other reports also state that this question is not yet decided. I therefore propose to say in the conclusions that as yet no definite opinion can be formed, or that a choice must be made in each individual case. On our railway system, we select the electric system in the case of small installations; but we prefer the electro-pneumatic system in the case of large installations, particularly when one single installation can be utilized for several central apparatus.

Mr. Verdeyen. (In French.) — I think that the remark made by Mr. Maas leads to the elimination of the clause in the conclusions stating : " A similar tendency has been found in Europe ", that is to say, the tendency of introducing more and more the use of electrically-operated apparatus. But, by agreement with Mr. Ulbricht, we have proposed to modify this wording as follows : " In Europe, electrically-operated installations at present preponderate among power installations ".

This is a record of fact.

The President. (In French.) — Does this wording satisfy Mr. Maas?

Mr. Maas-Geesteranus. (In French.) — Perfectly, Sir.

Mr. Petri, ministry of public works, Germany. (In German.) — Before passing to the discussion of littera *B*, I would draw attention, as regards the interesting reports which have been submitted to us, to a point which seems to me of particular interest, seeing the continual increase in the speed of trains. Mr. Ulbricht has already mentioned this point, leaving it to us to discuss it. Mr. Ulbricht's report, under question 59, gives us some information about arrangements provided for giving addditional security against the risk of over-running a signal, if the driver is careless. In his paper, the reporter, in considering this question, states that in order to prevent the over-running of signals, many very varied experiments have been made during the last tens of years so as to induce the driver to observe the optical signals, by means of some auxiliary means with a powerful action. He then mentions ths experiments made during the last ten years in Germany; in these the main feature is the use, in addition to the optical signals, of some automatically-acting device placed on the locomotive, intended to help the driver in the observation of the signal, by setting into action a steam whistle, a bell, etc., in other words, by providing an additional signal.

It is of course necessary that the driver should not enter dangerous sections, especially those with switches proceeded by signals, unless those signals stand at " line clear ". Greater safety would be obtained by means of devices which would prevent the driver from inadvertently over-running a signal standing at " danger ", that is to say, from passing it without observing it; for this can result in serious danger. During the last ten years many experiments have been made in Germany with devices giving on the locomotive an audible signal, corresponding with the position of the optical signals. But as yet no device has been found which has proved to be sufficiently reliable in its action.

We know that for long years experiments have also been made in other countries so as to obtain this new guarantee of safety, of giving an acoustic signal on the locomotive itself.

Now it would be of great interest to learn whether the experiments made in other countries have led to the discovery of a really reliable device giving entirely satisfactory results in practice, even when atmospheric conditions are unfavourable. If we could, in answer to question 59 of Mr. Ulbricht's report, obtain any information about this point, I think that we should elucidate a question of very great importance, in view of the increasing speed

of trains and the greater number of times the driver has to observe signals.

Mr. d'Abramson, Russian State Railway. (In German.) — I can inform you that on the Russian South Western Railway we adopted, four years ago, a device of this kind which is however not used in a general way ; I mean to say that it is only used in times of fog or of snow. It is an apparatus set in action by the station-master when it seems to him that fog or other unfavourable atmospheric conditions make this advisable. This apparatus has during these years given good results. We started with the principle that these automatic devices generally result in blunting the attention of the train employees and that great care must consequently be taken in their introduction. This is why we have adopted a device which only works when conditions are particularly dangerous.

Mr. Weissenbruch, *reporter*. (In French.) — We can but thank Messrs. Petri and d'Abramson for the information they have given us about the appliances repeating on the locomotive the track signals.

I will, however, venture to remark that this question does not fall within the scope of the question set before us. Accordingly we have not mentioned it in our report.

Mr. Ulbricht, utilizing the liberty left to the reporters, has thought it advisable to extend the scope of his observations and to consider the question of such repetition signals.

If the meeting thinks it advisable to consider it, I could in my turn give you some information concerning Belgium.

The President. (In German.) — This is in fact a question which we could probably not exhaust today, even if we had before us the answers of the different administrations; but, on the other hand, it is of such importance from the point of view of safety that no doubt it will continue to attract the attention of all administrations ; we may accordingly be able to recommend that it should be inserted among the agenda for the next session of the Congress. Mr. Petri states he agrees with this.

I now call upon Mr. Ulbricht.

Mr. Ulbricht. (In German.) — The reason why I have investigated this point in my report, and included it in the question I had to report about, was as follows : a signal placed on a locomotive and operated from a signal-cabin, by the intermediacy of the various means of transmission, is really to a signal operated from the signal-cabin. In fact, in the case of the van Braam and of certain other systems, the signalman, from his cabin, operates a signal on the locomotive, just as he operates a signal on the track. The zone of influence of the central apparatus thus extends in this case to the locomotive, and one can include any improvement in this system among the improvements made in signalling installations generally.

If everything regarding hand-operated apparatus is postponed to next session, we can but congratulate ourselves on this. As for me, I would remark that Mr. Petri's proposal is a particularly happy one and that many other members of this section would perhaps like to have fuller information about the subject; I do not

hesitate to say that I am included amongst them. The direct action of the signalman on the driver is a question which we shall have carefully to consider from now onwards. The five years which will elapse till the next session of the Congress are rather too long a period. Would it not be advisable to devote a quarter of an hour to this question already to day ?

Mr. Petri. (In French) — It would also be useful, in my opinion, to receive some information.

The President. (In French.) — We all agree that we cannot prevent anybody from giving information about any important point.

Mr. Descubes, French Eastern Railway. (In French.) — If we pass in this way from one question to another, the discussion will become confused and it will be difficult to arrive at any conclusion.

I therefore propose that we should first conclude the examination of Messrs. Weissenbruch and Verdeyen's conclusions before considering any other point.

Mr. Weissenbruch. (In French.) — I support the proposal made by Mr. Descubes to consider the question of repetition signals on the locomotive, at the end of the discussion.

I shall also have a communication to make.

Mr. Maison. (In French.) — The question can be considered after the discussion of Messrs. Weissenbruch and Verdeyen's report. This point is not in the programme, but every one of us may have some useful information to give. It seems to me inadvisable to postpone the consideration of this question to the next session.

The President. (In German.) — The discussion shows that there is a desire to consider this question at the end of the meeting. (*Approval.*)

We accordingly continue the general discussion of littera *A* of Messrs. Weissenbruch and Verdeyen's conclusions.

I call upon Mr. Descubes.

Mr. Descubes. (In French.) — Gentlemen, in reading Messrs. Weissenbruch and Verdeyen's report, delegates who are not aware of the strong movement there has been in France, during the last ten years, in favour of route-levers, might think that we have been satisfied with repeating the old trials made in Germany fifteen years ago and then given up. We find, in fact, on page 171 (1) the following phrase :

> In France several Companies and in particular the French Midi Railway, the French Eastern Railway and the French Northern Railway are following up the trials made and abandoned in Germany in 1895 of the appliances of Westend, Untertürkheim and Dresden, for operating all the points and signals of one route by a single lever.

I am sure that it has not for a moment entered the minds of the reporters to accuse French engineers of a plagiarism which is quite foreign to their habits.

Mr. Weissenbruch. (In French.) — Certainly not.

---

(1) See also *Bulletin of the Railway Congress,* July, 1910, p. 3345.

Mr. Descubes. (In French.) — I felt certain of it, but nevertheless I think I must go into this question thoroughly.

The idea of route levers is a simple one, which must have occurred to most engineers occupied with signals since power signalling, which made it possible to have recourse no longer to manual labour, became practicable. As soon as the Bianchi & Servettaz apparatus became used by several companies, the Rodary & Ducousso dynamos by the Paris-Lyons-Mediterranean, the Westinghouse motors by the French Eastern, and the Taylor by the Ceinture, the question of routes arose in France and resulted in a number of solutions differing among themselves and which no doubt are again different from the solution tried in Germany.

Mr. Weissenbruch. (In French.) — We certainly only intended to say that the general notion was the same.

Mr. Descubes. (In French.) — The report nevertheless, in a note, contains the following statement :

The German patent No. 83559 taken out by Siemens Brothers' but now expired, we believe, expresses this principle in terms remarkably similar to those used in Mr. Bleynie's specification.

Mr. Weissenbruch. (In French.) — " The *principle* ", that is the *general notion*.

Mr. Descubes. (In French.) — I wish to remark that when I began my investigation, I was totally ignorant of what had been done in this way abroad, just as I was totally unaware of Mr. Bleynie's investigations which soon afterwards were applied at Bordeaux.

I regret that Mr. Bleynie is not a delegate at the Berne session; he certainly would have made a similar declaration and would have convinced you that he was not merely satisfied with the Siemens patent as footnote 2 on page 171 might show. If that had been the case, there is no doubt that the Berlin *Patentamt* would have refused to grant him a patent. Now I have heard this very morning that this German patent was issued 11 December 1901, as No. 150535. Moreover, in this case, the way in which the result is obtained is of considerable importance, and very different apparatus can be based on the same principles.

If, for instance, we take, on the one hand, the Bleynie & Ducousso apparatus, and, on the other hand, the M. D. M. apparatus of the French Northern Railway, we find that each of them includes a lever per route, that this lever controls parallel switches by means of an electric contact or a compressed-air distributor per switch, and that the control is in series, always by means of a contact or of a pneumatic distributor per switch. However, the arrangement of the board and the control show appreciable differences.

In any case, as regards the system used on the French Eastern, I do not think that any similarity could be found in previous attempts, either in principle or in execution; no railway company nor administration has had, as far as I know, the idea of controlling the routes by means of a board with levers corresponding, the one, to the entering line, the other, to the departing line.

The Berlin *Patentamt*, whose scruples you all know, has however thought that it could grant a patent for this system, on 16 August 1904, No. 182727; and it cer-

tainly would not have done this if an earlier German patent existed.

Secondly, I wish to state that the word " trials " and above all " recent trials " can hardly, it seems to me, be applied to installations at stations where there is a very busy traffic, such as Bordeaux, Nancy, Valenciennes, particularly when those trials go back to more than seven years ago, as at Bordeaux or to even fifteen months, as at Nancy.

Whatever opinion may be held as to the value of these route appliances, they must be considered as beyond the experimental stage, and, contrary to what is stated on page 172 of the report (1), we have all the information necessary " to enable us to draw definite conclusions as to the efficaceousness of the appliances ".

I now pass to the remarks made on pages 172 and 173 :

1° The reporters think that the French engineers have been hypnotized by the fear of a strike. That is a complete mistake, for what we have tried to obtain above all is a simplification of the operations, a reduction in the labour and an increase in the capacity of a cabin.

Mr. Bleynie, it is true, did talk in a note about strikes, but that is a secondary argument which would certainly not suffice to justify the adoption of a system.

The reporters add that the apprenticeship of the signalmen who are to work at a central apparatus with ordinary levers is neither complicated nor difficult. The same remark is made in the proposed conclusion where it is stated, page 182 (2): " the end in view is that of rendering more easy the apprenticeship of the signalmen ".

These opinions appeared to me singularly optimistic, when I found on page 176 (1) the statement that an apprenticeship of from two to four weeks is estimated to be required for a man selected from " the more intelligent of the employees, provided that they were conversant with the traffic of the station which they had to work ".

I agree with the reporters as to this last estimate.

I will add that, as a rule, during these weeks of apprenticeship there is a considerable reduction in the output of work in the new cabins, and that is a fact which you have all observed.

When on the contrary, I put in service cabin No. 4 at Nancy, the signalmen who had never been in this cabin did not take a day before getting used to it. The next day already, half an hour was gained in the time of operating. Yet the zone of action of the cabin had been materially increased; it had to look after the passenger and goods trains going towards Strasburg, Epinal, Mirecourt, all the locomotives going back to the sheds or coming from them, and a large number of sets of empty passenger carriages, either for clearing them or for making up trains.

2° Secondly, the reporters think that cabins with individual levers are more convenient when it is necessary to operate a track appliance singly for purposes of inspection or of maintenance. Now the cabins of Bordeaux, like those of Nancy, include individual commutators and the

(1) See also *Bulletin of the Railway Congress*, July, 1910, p. 3346.

(2) See also *Bulletin of the Railway Congress*, July, 1910, p. 3356.

(1) See also *Bulletin of the Railway Congress*, July, 1910, p. 3350.

cutting out of an appliance presents no difficulty.

In order to avoid any disturbances, lead-sealed apparatus are used which work perfectly satisfactorily.

Mr. Weissenbruch. (In French.) — Is the safety the same?

Mr. Descubes. (In French.) — Absolutely. If the signal is not in the proper position, it cannot be opened.

Mr. Weissenbruch. (In French.) — Once the seals are gone, the interlocking is done away with. This is the position until the electrician has arrived at the cabin to re-seal the apparatus. Consequently that is not the same thing.

Mr. Descubes. (In French.) — 3° According to this remark, the economy of time is illusory.

It would be difficult to make one believe that it is as quick to operate in succession perhaps five or six switch levers, a route handle and a signal lever, as to operate one or two levers only.

In fact at Nancy not more than five seconds are required to make a route, to lock the switches and to set the signal to " line clear ".

I may be told that a difference of five seconds is negligible; but in the first place we must double this figure in order to allow for returning to the normal position. In the second place, when three or four movements have to be made simultaneously, a total difference of ten seconds in time of operation is of importance.

On the French Eastern Railway the traffic department which had so to say had nothing to do with the construction of the cabins at Nancy and thus was quite unprejudiced, took into consideration, before asking to have its cabins developed, the consequences from the point of view of safety, and of the facility and quickness of operation of the apparatus, of the output of work and of the expense.

I will ask your permission to read some of the conclusions of the report of the engineer charged with making these inquiries :

... Cabins D show a remarkable simplicity and ease of operation. It is enough, in fact, for the signalman to know where given vehicles come from and whither they are going, to make a route merely by operating two levers without any effort. The quickness of the operation is not reduced, seeing that all the switches concerned in a given route are operated simultaneously and that the throwing-over of points is so to say instantaneous.

... These cabins also have the great advantage of increasing very appreciably the traffic capacity of the stations. The considerable reduction in the number of the levers, together with the quickness and the ease with which the routes are made, make it possible to give such cabins a zone of action which is very great. Now from the point of view of the traffic capacity of a station, it is very advantageous to concentrate the whole work in the hands of a single signalman.

... The operations are carried out under safer conditions and much more quickly than formerly.

I may add that at Nancy the saving amounts to having ten switchmen less; on the other hand, we have three electricians. Thus there are seven employees less.

The end of the report says :

The results given by this system at Nancy are all the more remarkable as the cabin to which it has been applied is certainly not very suitable for it.

It accordingly seems that it would be advisable to adopt it for large cabins where much traffic has to be dealt with.

In France one objection has been raised to these route cabins, which I am surprised not to find in the report. It has been said that clearing treadles were required, and consequently operations were lengthened by the necessity of clearing a route completely. This criticism can be equally addressed to the system with individual levers and clearing treadles. But this disadvantage can easily be overcome by using, as we do at Nancy, operating commutators which make it possible to break up the route before the treadle is cleared and which, in a second movement, lock the new route which is made.

Mr. Verdeyen. (In French.) — That is also done in Belgium.

Mr. Descubes. (In French.) — In order not to prolong this explanation, I will later on answer a few words to remarks 4° and 5°.

I will conclude this discussion by mentioning the advantages which I think route levers possess :

1° In the first place, I must mention simplicity of operation. With the Bleynie system, or with the M. D. M. system, one operates one lever. With the Nancy system, one operates two : that of the track of entry and that of the track of departure ; that is to say, the signalman has only to note down in the simplest manner the order he has received by telephone from the station or from the official in command.

This results in a reduction in the mental effort, which the reporters mention with justice in their remark 4°, page 173 [1];

2° Interlocking from cabin to cabin, the protection of trains stopping at a station, can be realized more easily than with any other system. This is what has been done with a simple commutator at Nancy, where the route can be blocked as regards arrival, while remaining free for departure;

3° Operation is quicker, and consequently the output of the station is increased, as experience has shown. I will not return to this point which I have dealt with at length;

4° From the point of view of the working expenses, we have to consider the maintenance proper and the cost of the staff. As regards the former, it is clear that the cost of maintenance of the motors and of the apparatus itself must be practically the same, whatever the system, but the cost of current may be lower in the case of route apparatus. In fact, in the latter system, it is possible to cut off entirely the operating current and the control current of a switch whenever no route affecting that switch is made; this also has the advantage that the conductors of the motors do not remain charged.

These two conditions are, it is true, satisfied by the Siemens Brothers apparatus, but not by the Siemens & Halske apparatus.

As regards the cost of the staff, it can only be less in the case of the route apparatus, at least at important cabins, where several signalmen are required if individual levers are used.

In fact, on the one hand, operations are

---

[1] See also *Bulletin of the Railway Congress*, July, 1910, p. 3347.

carried out more quickly; on the other, the size of the cabin can be appreciably reduced by reducing the number of levers.

In order to make this clear, I will take as an instance a cabin which we are at present designing for a central station, where we will have to operate 102 switches and 61 signals and where the number of routes possible, including diversions, is exactly 200 in each direction. With a Saxby cabin, there would be necessary a frame of 187 working levers, including the lock levers. If we took the latest type of Siemens & Halske apparatus mentioned on page 161 (1), there would be necessary, if I understand the description properly, 65 point levers, 200 route handles, total 265. With the Nancy system, 64 levers suffice.

All these reasons make it impossible for us to accept the conclusions in the report which seem to us too severe.

Mr. Weissenbruch. (In French.) — I should like to say a few words in answer to the remarks made by Mr. Descubes. But as it is already late, I will do so at this afternoon's meeting.

Meeting held on 9 July, 1910 (afternoon).

Mr. Weissenbruch, *reporter*. (In French.) — As against what Mr. Descubes seems to think, I must assert that we did not for a single moment intend to accuse the inventors of the French apparatus of plagiarism. It is true that we have recalled the trials made in Germany in 1895, and then given up, but we have only had in view a question of principle and we have not wished to dispute the originality of the French apparatus. In fact, the idea of operating several switches by the movement of one single lever must have occurred to all those who occupied themselves with the question of switches and signals.

The phrase which is found on page 171 of our report and which Mr. Descubes has criticized is but the summary of a passage in a note, describing the installation of Antwerp, published in the *Bulletin of the Railway Congress*, August 1904, p. 667.

This passage is as follows :

The principle of Mr. Bleynie's system is that only one movement of a lever is necessary for each train. The movement of the lever includes two parts. In the first, the switches are operated. When these have assumed the required position, a controlling current releases the lever and makes it possible to move it further; this places the corresponding signals to safety and clears the line. The disavantage is that, in order to make it possible to act in case of any failure, it is necessary to have an emergency commutator in the cabin making it possible to operate all the switches and signals independently. This commutator is placed behind a glazed door, of which the station master keeps the key, and it is forbidden to use the main apparatus when the emergency apparatus is in use; but we know how difficult it is to ensure that such rules are never broken.

Experience is already available on this point. Messrs. Siemens and Halske patented in 1895 (2) a similar system which could easily be applied to their old patterns of cen-

---

(1) See also *Bulletin of the Railway Congress*, July, 1910, p. 3335.

(2) German patent No. 83559.

tral apparatus at Westend, Untertürkheim and Dresden. All the switches concerned in a given route were operated at once by the route lever, and all the signals by another lever.

These paragraphs prove that we did not for a single instant wish to cast any doubt on the originality of the apparatus tried in France. We merely remarked that trials based on the same principle had been made previously in Germany.

Moreover, in the same report we have fully acknowledged the ingenuity of the French apparatus, for on page 173 (1) we say :

> We think that we may conclude that, *in spite of the ingenuity which has been devised with a view to substituting route operation for single lever working*, the advantages of the latter system are such that owing to the conditions of the problem to be solved, they will finally prevail.

The whole question comes down to this : our opinion differs from that of certain French engineers and we continue to believe that with individual levers the same practical results can be obtained as with route levers, without the complications that the latter involve.

As regards the expression " recent trials ", that refers purely to the Descubes system and to the M. D. M. apparatus, tried respectively at Nancy station and at Paris-Nord. According to Mr. Descubes' own statement, the Nancy trials now date back fifteen months. So then they were recent at the time we prepared our report.

(1) See also *Bulletin of the Railway Congress*, July, 1910, p. 3347.

Mr. Descubes has also referred to the following passage on page 176 (1) :

> An apprenticeship of from two to four weeks according to the magnitude of the installation has been found amply sufficient to familiarise them with the operation of the appliances, since this is generally much more simple than that of mechanically operated appliances.

In this connection, we can give him some fresh information. This period of two to four weeks is a very relative matter. We meant to say that before putting the new apparatus into use in Belgium, we placed the signalmen during this time in the cabin, *when it was possible to do so*. At Alost we simply placed the signalmen *in the station* for a fortnight and we made them acquainted in advance with the plan of the station, with the location of the switches and the signals, and their numbering. It was only possible to make them enter the cabin, in order to learn the work, twenty-four hours before it was used. Everything went well, for there was no appreciable delay in the movement of the trains from the time that the new installation was put in service.

Mr. Verdeyen, *reporter*. (In French.) — Mr. Descubes has said that there is a means of avoiding any disturbances by having lead-sealed appliances near the signalmen.

As for us, we think individual operation is preferable, seeing that in case of the failure of a switch, one can go on with the regular operation of the central apparatus and still have the guarantee of the mechan-

(1) See also *Bulletin of the Railway Congress*, July, 1910, p. 3350.

ical interlocking of the cabin. Attention need only then be given to one broken-down switch.

On the other hand, if one operates with arrangements normally sealed, any mistake is possible, for there is no longer any interlocking.

As regards the new M. D. M. system, I have had the opportunity of seeing the apparatus while being made at the workshops of the Aster Company; I had remarked that it would be easy to operate the switches by means of individual switches. I saw with satisfaction, at the Brussels exhibition, that the Aster Company had applied to an apparatus of this kind a device making individual operation normally possible.

Mr. Tettelin, French Northern Railway. (In French.) — That had been decided in advance.

Mr. Verdeyen. (In French.) — I was not so informed at the time I paid my visit.

According to Mr. Descubes, not more than five seconds are required, at Nancy, for making a route, locking the switches and setting the signal. We have stated that eight seconds are required with the Belgian electric apparatus with individual operation.

In connection with this point, we may remark that in order to make a route, it is evidently necessary to have : 1° the time required for operating the switchçs and for the action of the control current; 2° the time required for operating the signals so that they may show " line clear ".

Now a switch is operated in the same time, whether we use a route lever or an individual lever; the motor must have time to complete its travel. The time required for this is two to three seconds, in the case of all the electric systems known. Then we must also allow two to three seconds for setting the signal to " line clear ". In Belgium, we need two seconds more, because all the routes have two signals, and the one at the end of the route must be set before the one at the beginning of the route. If the same signalling principles were applied to the French apparatus, it would accordingly be necessary to add two seconds to the figure given by Mr. Descubes. *Consequently the difference of time is only one second.* It corresponds to the actual time necessary for operating the switch levers.

As to the statement made by Mr. Descubes that 187 Saxby levers, which could be replaced by 64 Descubes levers, would require 265 levers with the apparatus in use in Belgium, we think that we may assert that we would succeed in reducing this figure of 265 if we utilized all the resources of the Belgian system. We have always succeeded in reducing the number of the electric levers as compared with that of the Saxby levers necessary for one and the same installation. At Alost, 144 electric levers do the work of 381 Saxby levers.

Mr. Weissenbruch. (In French.) — The opinion in favour of individual operation, which we have expressed in our report, is our own personal opinion ; it is not an opinion derived from the replies to our list of questions and we have not pronounced categorically in favour of the one or of the other system. We have limited ourselves to giving our opinion as engineers, members of the Congress, just as we

might have done during the course of the discussion. Hence, the reproach which has been made, but not at this meeting, that I had the report distributed too late is unfounded.

Mr. Verdeyen and I, having of late been overworked in our capacity as engineers of the Belgian State Railway, did not have the time to finish our report sooner.

Moreover, you all know that several other reports also only appeared at the last moment.

Mr. Heurteau, Orleans Railway. (In French.) — Mr. Weissenbruch has just referred to the reproach addressed to him, outside the meeting, of not having had his report distributed sooner.

It is I who addressed this reproach to him and I wish to repeat it publicly.

I regret that this report reached us so late. This regret is all the more well-founded as the General Secretary has urged all the reporters to do their work as soon as possible.

On the other hand, I must protest against certain passages in the report, in which the system applied by the French engineers is criticized in a way which seems to me to be partial and unfair.

If the Midi Railway Company had been aware of this in good time, it would have delegated Mr. Bleynie to answer Messrs Weissenbruch and Verdeyen's statements.

Mr. Weissenbruch. (In French.) — I much regret that it was impossible for us to finish our report sooner, and I once more apologize for this. But I must protest against Mr. Heurteau's words, and I see nothing unfair except his words. Many other reports came in very late. Is the General Secretary to be reproached for having, in deference to his colleagues, had their reports printed before his own?

Much greater delays have occurred at other sessions; thus I may mention that at Paris, in 1900, Messrs. Auvert and Mazen's report was handed in *after the session had begun*, and that the French companies strongly urged that it should be printed as quickly as possible, although the Permanent Commission had decided not to take into consideration reports which were received so late.

Mr. Heurteau has just said that we have been partial, in an unfair manner, in the case of the system applied by the French engineers. I regret that he has made use of such an expression. It is not our habit to show partiality towards anybody in an unfair manner; to say so is to misunderstand our character.

However, that may be, I am glad to be able to take the opportunity of this attack to affirm categorically that such has never been our intention.

If Mr. Heurteau alludes to the passage Mr. Descubes referred to, I will repeat what I have already said. That passage is only the summary of a note which one of us published in 1904 in the *Bulletin of the Railway Congress*. Mr. Bleynie, whose name was mentioned therein, has had plenty of time to answer it since.

Mr. Heurteau. (In French.) — I do not know what your intentions were, but if Mr. Bleynie could have seen your report in good time, he would have come here in order to answer the note given on page 171 [1] which was unfair to him :

The German patent No. 83,559 taken out

[1] See also *Bulletin of the Railway Congress*, July, 1910, p. 3315.

by Siemens Brothers' but now expired, we believe, expresses this principle in terms remarkably similar to those used in Mr. Bleynie's specification.

Mr. Weissenbruch. (In French.) — We have said : " this principle... " At page 160 of the report (1) full details are given of the chief points in Mr. Bleynie's system.

Mr. Heurteau. (In French.) — It is a question of what is discussed at the Congress. If your report had been issued in good time, Mr. Bleynie would have come here to answer you.

The President. (In French.) — It follows from the remarks which have been interchanged, that Messrs. Weissenbruch and Verdeyen had not the least intention in the world of criticizing the French engineers.

This incident is accordingly closed and I call upon Mr. Tettelin.

Mr. Tettelin. (In French.) — Gentlemen, I wish to draw your attention to that part of Messrs. Weissenbruch and Verdeyen's report in which they examine the question of the eventual generalization of the system of operation by route levers, They think that individual levers will in the long run be preferred to route levers and they draw these conclusions from five propositions which may be summed up as follows :

1° The apprenticeship of the signalmen is neither more complicated nor more difficult with the individual lever than with the route lever, if one has men who know the regular train service in the zone they have to look after;

2° The making of a route when one has a system of route levers results but in an imaginary saving of time, as compared with a system with individual levers operated at the same time;

3° and 4° One cannot hope to realize a saving, either in operating staff or in maintenance staff, by using the route lever instead of the individual lever.

Mr. Descubes has discussed these first four propositions this morning and I entirely share his opinions in this respect. I therefore will not stop to dispute their value. I will simply say that they form no argument against the route lever; these propositions in fact tend to show not that the individual lever is superior to the route lever, but simply that it is not inferior to it.

There remains the fifth proposition which is of a different nature. It is this : in case of damage, or in case of breakdowns it is often necessary to operate a given track appliance separately, and this can be done much more easily in the case of the individual-lever system than in that of the route-lever system. This argument is put out of court if the central cabin is arranged in such a way, that while operating with route levers, it is also possible, in case of necessity, to operate any switch or signal separately, *with all safety*. That is so, moreover, in the case of three of the route-lever systems described in the report; namely the Bleynie, the Descubes and the M. D. M. systems.

It is accordingly with some surprise that I see the reporters say after those five propositions :

We think that we may conclude that, in spite of the ingenuity which has been devised with a view to substituting route operation

(1) See also *Bulletin of the Railway Congress*, July, 1910, p. 3334.

*

for single lever working, the advantages of the latter system are such that owing to the conditions of the problem to be solved, they will finally prevail.

What troubles me about this conclusion, is that not only is it difficult to deduce it from the premises, but that above all it seems to me to misunderstand the origin, the importance and the future of the route lever.

What led, gentlemen, to the idea of the route lever? The desire of simplifying, and consequently, of facilitating the work of the signalmen. What does in fact the operator want? It is the power of making a route by means of as few operations as possible, and if the engineer did not at once satisfy this desire, it was because he was stopped by material difficulties; the engineer in the first place supplied the operator with separate levers, placed near each track appliance; then he grouped the levers together in a central cabin, and he succeeded in adding interlocking, to the great benefit of the operator. Then he made a single lever operate the two appliances of a cross-over; this idea, which reduces the work of the signalmen, contained the germ of the route lever. That the latter type was not evolved sooner is not at all due to the fact that the operator did not desire it; it was simply due to the fact that the engineer did not know how to do it.

Would it be reasonable, in fact, to compel the signalman to operate three or four levers, for instance, the day when it is possible to obtain a good result by only operating one lever? When a signalman has to deal with 500 trains or locomotives per day, is it not a great advantage to him to do this by 1,000 lever pulls instead of 3,000 or 4,000? And what operator would refuse to have his work lightened to this extent?

Hence, it is evident that the individual-lever system is but a step on the road towards the desirable route-lever system, and that step will necessarily be taken the day the engineer succeeds in obtaining the latter solution in a satisfactory manner.

I accordingly turn to the engineers, and ask them : do you think that the route lever will not in the long run be preferred to the individual lever, that is to say, that the problem of proper design, which is all that remains, cannot be solved? Can it be maintained, seeing past progress, that this improvement cannot be made? All the less can this be done, as the problem has already been tackled in various ways, and I think I may say, to judge by the results of the M. D. M. system, which the French Northern has investigated and installed, — and with which I am best acquainted — that this improvement has now been realized.

This apparatus M. D. M. (" *minimum de manœuvres* "), with its route lever, moreover, makes it possible, as the reporters specify with reason, to operate a single appliance, in case of necessity, with all safety. For each route, there is only one lever which simultaneously (not successively) operates all the switches and then sets the signal after the position of the switches has been automatically controlled. Finally, this control continues to exist as long as the signal stands at " line clear ".

The most remarkable feature is that the apparatus, known as the route-combiner, through which the levers act on the switches and levers, is designed in such a

way that it *automatically*, by its construction, realizes the necessary and sufficient interlocking of the levers, so that it is no longer necessary to make that careful and detailed investigation of the interlocking, required in the case of all the other systems.

You understand me : there is no longer any locking table and this leads to so much mechanical simplification that merely from the point of view of the engineer this is an enormous progress. This, moreover, has a very interesting result when it becomes necessary to rearrange the tracks or signals in the zone served by the cabin. In the case of the other systems, it is at the same time necessary to rearrange the interlocking, and that is a long, delicate and very disagreeable piece of work, for while it is being carried out, the ordinary guarantees of safety are non-existent, either altogether or partly. Both the operator and the engineer equally desire the disappearance of this critical period.

Well, the property the new apparatus has of realizing by construction all the interlocking necessary gives this result, that if one adds or if one takes away a lever — and this is done in a few seconds — the interlocking remains.

The alterations to be made in the cabin, in order to pass from the old conditions to the new, are accordingly made without at all affecting the actual safety.

That is a result which very much exceeds the modest advantages which were expected from the route lever, and the engineer finds this an advantage as well as the operator, for he obtains a much simpler and less cumbersome apparatus than those which existed before. In this branch, as in many others, the earlier solutions were complicated and it is by simplifying them that one succeeds in improving them.

There lies the future.

The M. D. M. apparatus which I have alluded to was not yet evolved in this new form when Messrs. Weissenbruch and Verdeyen drew up their report; that described by them is the primitive type and the new one differs radically.

I place on the table a short description of this apparatus (see appendix II) and I am quite ready to give those of my colleagues who are interested in the subject, any further information which they may require. (*Applause from some benches.*)

Mr. Weissenbruch. (In French.) — The normal state of affairs does not always exist at a station. Moments arrive when the switches are out of order, and as Mr. Verdeyen has stated, the route lever may involve disadvantages in such a case, while the individual lever makes it possible to continue the regular operation of the central apparatus, while maintaining the guarantee of the mechanical interlocking of the cabin.

The ideal would be an apparatus combining the advantages of the route lever with those of tha individual lever.

Mr. Verdeyen. (In French.) — I note that Mr. Tettelin agrees with us on most of the points. He has recognized, in fact, that the two systems are of equal value.

Moreover, he considers that it is an appreciable advantage of the new type of the M. D. M. system that it is possible to operate the switches individually, while retaining the safety due to mechanical interlocking. He accordingly recognizes that

the other apparatus in use in France do not realize this condition which we think absolutely indispensable in order to ensure, even in case of break-downs, the safety of the train service.

Mr. Tettelin. (In French.) — I am far from agreeing with you and considering the two systems as of equal value.

I have on the contrary shown that your arguments did not justify you in concluding that the individual lever will in the long run be preferred to the route lever, and I have expressed the opinion that the future belongs to the latter.

Mr. Verdeyen. (In French.) — We have said that the advantages of the individual lever are, in our opinion, superior to those of the route lever, taking into consideration the problem which has to be solved and the elementary conditions of safety which have to be ensured at all times and particularly in the case of break-downs.

Mr. Descubes. (In French.) — The result of this discussion is that the opinion of the reporters about those two points is unshaken.

As regards break-downs, the Nancy apparatus makes it possible do deal with them without endangering the safety. In fact by operating this apparatus, the signalman is perfectly able to make the routes in case of a break-down. I will demonstrate this whenever desired, but that is a question which it is better to discuss privately.

Mr. Weissenbruch. (In French.) — The signalman can make routes without interlocking, that is to say, without any guarantee of safety. Therein lies a question of principle. Any demonstration would be useless.

Mr. Descubes. (In French.) — As for the speed of operation, Mr. Verdeyen has given us an ingenious calculation to show it is as easy to operate with two levers as with one.

He has not convinced me and I also have no expectation of making him change his opinion. Moreover, if one considers the matter well, in the light of the explanation given about the apparatus used in Belgium, one perceives that the latter are nothing but route apparatus to which individual levers have been added, with the obligation of operating the latter before the former.

In Belgium, the route lever is not operated until after the switches have been operated. As for us, we limit ourselves simply to the operation of the route lever.

Under these conditions, I do not understand the somewhat summary way in which the reporters have dealt with the route-lever system which they have seen at work in Paris and which is much appreciated on the systems of the French Eastern, the Orleans, the French Northern and the Midi. Four French railway companies with 25,000 kilometres (15,500 miles) of track accordingly prefer it.

Mr. Verdeyen. (In French.) — What should be considered is the number of stations equipped with the improved apparatus and not the mileages of the railway systems.

From what you have just said, you acknowledge yourself that the French route levers are nothing but an extreme extension of the Belgian route levers.

Mr. Descubes. (In French.) — It is by no means my intention to force our system on the Belgian railways; but it should not be stated in the conclusions that the individual lever is superior to the route lever and that the latter is still a subject of trial.

Mr. Weissenbruch. (In French.) — We do not say this, but we maintain that the advantages of the French route levers do not make up for the complication they entail.

Mr. Tettelin. (In French.) — Indeed you do, on page 182 (1).

Mr. Descubes. (In French.) — I will again read out the sentence in the conclusions of the report:

In France, trials are in progress with a view to operating all the points of a route by means of a single lever. The end in view is that of rendering more easy the apprenticeship af the signalmen.. In Germany and in Belgium attempts to operate points simultaneously, other than those usually worked in combination for a cross-over, have been given up. In those countries, it is thought that the apprenticeship of the signalmen can always be effected quickly if they are familiar with the traffic at the station and that apprenticeship is quite useless unless they are familiar with the traffic.

As I stated this morning, it is no longer a question of " trials " at Bordeaux, Nancy and Valenciennes stations; it is a question of *applications*.

According to the report, we are giving ourselves a lot of trouble in order to arrive at nothing.

Mr. Weissenbruch. (In French.) — We spoke of trials at Nancy where according to Mr. Descubes the appliances have been in use for fifteen months. In order to satisfy everybody, it would suffice to say : " In France, applications have been made so as to operate by means of a single lever all the switches of a given route ".

If we have been mistaken as to the object you have aimed at, we shall be pleased to mention it in the conclusions.

Mr. Tettelin. (In French.) — Can it be said in the conclusions that Belgium has given up the route lever, seeing that it has never tried it?

Mr. Weissenbruch. (In French.) — It was in Germany that, after trials, the route-lever system was given up, and the Belgian railways have come to the same conclusion as the German railways. We however attach no particular importance to this wording. Above all we desired to draw attention to this question and to have it discussed here, and we seem to have succeeded only too well.

Mr. Verdeyen. (In French.) — It is a question of principle, and in Germany the principle of the route lever has been given up.

Mr. Tettelin. (In French.) — Other apparatus are in question there.

Mr. Verdeyen. (In French.) — It is a question of the same principle. We have not discussed the apparatus.

It seems to me that the question of break-downs, such as we mean it, has not been understood. In the Belgian system, when there is any failure of a switch concerned in the route, the con-

(1) See also *Bulletin of the Railway Congress*, July, 1910, p. 3356.

trolling indication is not received in the cabin. However, nothing prevents the operation of the auxiliary route lever which mechanically locks all the switches of the route and keeps them immovable during the whole passage of the train, even when a switch is out of order. Moreover, as the cabin does not receive the controlling indication, it is impossible to set the signal to " line clear " and the operation must be ordered specially.

Mr. Descubes. (In French.) — The same is the case with us.

Mr. Verdeyen. (In French.) — Perhaps with the new M. D. M. system in which all the mechanical interlocking is maintained in operating the supplementary levers of individual switches in case of a break-down. But this new system, the only one based on this principle, did not exist when we drew up our report.

Mr. Weissenbruch. (In French.) — This is very important from our point of view and I add that with the help of the route lever which we have, we can operate individually the switch which is out of order while maintaining the safety of the other switches.

Mr. Descubes. (In French.) — The same is the case with us. If the wire is broken, one operates by hand.

Mr. Weissenbruch. (In French.) — That is not the case either at Paris or at Bordeaux.

Mr. Descubes. (In French.) — A route can only be given and a signal set if the switch is in the proper position.

Mr. Jullien. (In French.) — I wish to make a remark about two statements in the conclusions. The first is :

The methods of power supply most usually employed, are, on the one hand, electric current and, on the other, compressed air with electric indicating gear.

I see that no mention is made of hydro-dynamic working; there are ten such cabins which have been working without trouble for more than twenty years on the Orleans Railway.

Hence I propose that these cabins should equally be mentioned in the conclusions.

These hydro-dynamic cabins may not be perfection; but I may state that in our experience of twenty years they have given excellent results.

Here, moreover, is a fact which I can cite in their favour.

In the month of January, during the Seine floods, the apparatus of the signal-cabins at the Paris station remained for a week under 1 metre (3 ft. 3 in.) of water. Now the very day the flood subsided, all that was necessary was to clean the apparatus, and two hours later the cabins worked as well as before.

Our Italian colleagues can no doubt confirm my statements, for this apparatus is frequently used in their country.

I do not dispute that hydro-dynamic cabins are open to certain criticisms, but it is nevertheless true that till now they have not given any serious trouble.

Mr. Weissenbruch. (In French.) — We agree that the conclusions should be modified in the way recommended by Mr. Jullien.

Mr. Verdeyen. (In French.) — One might add : " the systems of water under pressure... "

Mr. Jullien. (In French.) — The second statement runs as follows :

In the United States of America, where the latter system (compressed air with electric indicating gear) first came into most general use, electricity has taken the lead in latter years, and it is probable that it will continue to keep the lead over its competitors for the following reasons :

1° This system is more easy of adaptation and use;

2° The losses due to storage and in the distribution are very small;

3° The distribution and utilization of electric power are independent of variations of temperature or of severe extreme temperatures.

A similar tendency has been found in Europe.

That should also be modified, for in opposition to the opinion of the reporters, I do not clearly see this marked preference in favour of electric apparatus expressed in Mr. Carter's report.

Mr. Verdeyen. (In French.) — This is the new wording which we propose : " Electrically-operated installations are at present preponderating among power-operated installations."

Mr. Descubes. (In French.) — Let us say " the most usual " instead of " preponderating."

Mr. Dufour. (In French.) — I have visited cabins on many railway systems, especially on the lines of the New York Central, where I have seen numerous applications of the Westinghouse system.

On the Dutch railways, both systems are being tried and I would be very puzzled to state which of the two is better.

Our colleague Mr. Matheson has published a note, in the *Proceedings of the Institution of Civil Engineers of London*, about Glasgow station, which I have also visited. It follows from this note that when the question was discussed, the engineers were very puzzled to give a decision.

Hence the question is far from settled.

Mr. Weissenbruch. (In French.) — As for Mr. Carter's opinion, we may consider it a weighty one, as our colleague also expresses his opinion about the electro-pneumatic system, of which he is an old partisan.

The conclusion of his report is formal. Here it is :

Summarizing the situation as regards interlocking in America :

Application of power interlocking is rapidly increasing;

Electro-pneumatic and purely electric systems are superseding all other forms of power interlocking.

Mr. Jullien. (In French.) — When Mr. Carter drew up this conclusion, it seems that his opinion was not very definitely settled, for he says :

Electro-pneumatic and purely electric systems are superseding all other forms of power interlocking.

Those words show that he makes a very justifiable reservation.

These cabins have only been in use a rather limited time and the results do not yet make it possible to give the preference to either system.

Mr. Weissenbruch. (In French.) — It must not be forgotten, in understanding Mr. Carter's report, that the electro-pneumatic system was already very widely applied in the United States at the time when the first electric systems appeared in that country.

Mr. Dmitrenko, Russian State Railway. (In Russian.) — I wish to remark that Mr. Ulbricht has not mentioned in his report — probably owing to delay in the answers of the Russian railways — that in Russia, apparatus with water under pressure and apparatus with carbonic acid are also used.

Mr. d'Abramson. (In German.) — I think it will also be of interest to add that in Russia, where the variations in temperature attain 75° C. (135° Fahr.) and where on certain lines, such as the Russian South Western, in the Caucasus and even on the Nicolas line (near Moscow), the thermometer falls to —35° C. (—31° Fahr.), the Bianchi and Servettaz system has been applied, very successfully, during more than fifteen years. I am accordingly of opinion that although perhaps the future may belong to the electric and the electro-pneumatic systems, it can nevertheless be said that the hydraulic system has much in its favour in the case of small installations.

On the other hand, as regards carbonic-acid apparatus, it must be recognized that as yet no good results have been obtained with this system in Bussia.

Mr. Segré, Italian State Railway. (In French.) — I completely agree with Mr. Jullien's statement, and declare that on the Italian railways the hydro-dynamic system has been in use for a long time, ever since the beginning. It has given such satisfactory results that its application is going to be extended in all great stations, as in that of Milan.

Mr. Dufour. (In French.) — I thank the French delegates for having supplied us with information about the route-lever system which is hardly known in the other European countries, especially Holland.

The conclusions submitted to us talk of the different methods of operating switches and signals, except as regards the double-wire system.

For instance, I read the following :

The use of the fluid operated central apparatus, principally for large stations, has made rapid progress during the last ten years. Such apparatus has the advantage of allowing of greater concentration, and, consequently, greater safety and greater rapidity of operation, while at the same time it renders more easy the work of the employees.

I do not think that there is greater safety than with double-wire apparatus. We use the latter in Holland and obtain excellent results.

The conclusions also state :

It is also possible to obtain greater safety in working the traffic by arranging for the clearing of the routes by the train itself, by indicating the true position of the points, by obtaining the return to normal or stop position of signals after the train has passed (or in case of any disturbance in the route run over), etc.

In nearly all the apparatus used in Holland, the same results are obtained by means of a battery current.

That sentence should accordingly be struck out of the conclusions.

Further on I read :

In large stations to which an electrician is permanently attached, the concentration has led to a reduction in the number of signalmen. By this means, it has been possible to recoup the expenditure in capital while at the same time greater safety has been obtained than that which was formerly given by the old mechanical installations.

And on page 175 of the report (1), the reporters compare the cost of installation of the Siemens & Halske system and that of the Saxby system. With the latter, the cost would only be 400,000 francs (£16,000), while with the former it was 440,000 francs (£19,600). I feel convinced that one could have adopted the double-wire system, with two cabins, and in that case the cost would only have been 200,000 francs (£8,000).

We also have double-wire cabins where the operations can easily be carried out by two signalmen and I think that two men would equally be required with electric operation.

Mr. Verdeyen. (In French.) — The figure of 400,000 francs (£16,000) quoted also includes all the additional safety appliances, consisting of electric apparatus, added to the Saxby system so as to realize the full advantages given by the electric operation of switches and signals. Hence, the figure of 200,000 francs (£8,000) given by Mr. Dufour for the double-wire installations would have to be materially increased, in order to allow for the carrying out of this programme and to make a comparison.

I however propose to modify the wording and say : " In very large stations... ", and to leave out the statement referring to increased capital expenditure.

Mr. Dufour. (In French.) — Exactly.

The President. (In French.) — As nobody else wishes to speak in the general discussion, we will proceed to examine the conclusions, the first paragraph of which runs as follows :

" Littera *A*. — The use of the fluid-operated central apparatus, principally for large stations, has made rapid progress during the last ten years. Such apparatus has the advantage of allowing of greater concentration, and, consequently, greater safety and greater rapidity of operation, while at the same time it renders more easy the work of the employees It is also possible to obtain greater safety in working the traffic by arranging for the clearing of the routes by the train itself, by indicating the true position of the points, by obtaining the return to normal or stop position of signals after the train has passed (or in case of any disturbance in the route run over), etc."

Mr. Jullien. (In French.) — Although we are not discussing the question of mechanical installations, it is advisable to say a word about them at the beginning of the conclusions.

I accordingly propose the following wording :

" Although hand-operated apparatus are by far the most common and give satisfaction, the use of fluid-operated central apparatus has made rapid progress during the last ten years or so, particularly at very large stations, etc."

Mr. Weissenbruch. (In French.) — It is also important to state that where current is available, the safety can be increased with hardly any extra expense, by having a few extra wires in the cables.

Mr. Gérardin, French Eastern Railway. (In French.) — That is a very minor point.

(1) See also *Bulletin of the Railway Congress*, July, 1910, p. 3349.

Mr. Weissenbruch. (In French.) — Nevertheless it is true that when operation is effected by means of electricity, one can have much greater safety without hardly any new expenditure.

At Brussels-Midi station, the Belgian State Railway has had to incur considerable expenditure in order to obtain complete safety by adding supplementary devices to the existing mechanical apparatus. If we had concentrated the whole into a single cabin by simply adopting electric operation, we would have effected an important saving in working expenses.

Mr. Gérardin. (In French.) — If one succeeded in finding the ideal cabin, one would not hesitate at the expense. It is not because there is already current that some supplementary contacts will be added.

The question of safety is more important than that of working.

Mr. Weissenbruch. (In French.) — At Brussels-Midi station we spent 200,000 francs (£8,000). Now with 300,000 francs (£12,000) we could have had a complete electric installation which would have enabled us, I repeat, to effect a considerable saving in working expenses.

The question of economy is actually of great importance, once the safety has practically been ensured. It is always this question which makes railways hesitate to adopt improved installations.

On the whole, we agree; but you are under the impression that increased safety can be obtained by means of a few accessory appliances, that is tosay, subject to a small expenditure. Now this is not the case when one wants to add to a mechanical installation all the advantages of safety which the electric systems afford.

Mr. Jullien. (In French.) — It would be preferable not to urge the question of the expenditure required in order to settle and obtain a control.

On the Orleans Railway, the investigations of this problem has shown us that the solution would not involve a large expenditure.

It is true that in an electric cabin it is technically very easy to obtain absolute control, but that is not a reason for condemning mechanical cabins from this point of view.

Mr. Gérardin. (In French.) — We must not condemn any system, but everybody must be left his liberty.

Mr. Jullien. (In French.) — One might say : " It makes it at the same time possible to obtain complete safety, etc."

The President. (In French.) — As nobody else wishes to speak, I propose that we should provisionally adopt the first paragraph as amended by Mr. Jullien. (*Approval.*)

These are the next clauses :

" The methods of power supply most usually employed, are, on the one hand, electric current, and, on the other compressed air with electric indicating gear.

" In the United States of America, where the latter system first came into most general use, electricity has taken the lead in latter years, and it is probable that it will continue to keep the lead over its competitors for the following reasons :

" 1° This system is more easy of adaptation and use;

" 2° The losses due to storage and in the distribution are very small;

" 3° The distribution and utilization of electric power are independent of variations of temperature or of severe extreme temperatures.

" In Europe, electrically-operated installations are the most used form among power-operated installations."

Mr. Descubes. (In French.) — I have proposed that in the last sentence the word " preponderating " should be replaced by " most usual ".

Mr. Gérardin. (In French.) — The word " preponderating " is too categorical.

— The wording, so amended, is provisionally adopted.

The President. (In French.) — This is the continuation of the conclusions :

" In the case of isolated appliances, carbonic acid gas has been used with success.

" In large stations to which an electrician is permanently attached, the concentration has led to a reduction in the number of signalmen. By this means, it has been possible to recoup the expenditure in capital while at the same time greater safety has been obtained than that which was formerly given by the old mechanical installations.

" In France, trials are in progress with a view to operating all the points of a route by means of a single lever. The end in view is that of rendering more easy the apprenticeship of the signalmen.

" In Germany and in Belgium, attempts to operate points simultaneously, other than those usually worked in combination for a cross-over, have been given up. In those countries it is thought that the apprenticeship of the signalmen can always be effected quickly if they are familiar with the traffic at the station and that apprenticeship in quite useless unless they are familiar with the traffic.

" Up to the present, the central electric installations have been operated by continuous current. Single phase alternating current and three-phase current have also been tried. Up to the present the following difficulties have been met with : difficulties of insulation, increased cost of the motor and of the electro-magnets, noise made by the motors when stopped, risk to the staff, and the impossibility of dispensing with accumulator storage."

Mr. Gérardin. (In French.) — I propose to replace this text by the following which corresponds to the truth :

" Since several years, applications have been made, in France, of route-lever apparatus. Attempts have been made, by means of these apparatus, to simplify the regular work of the signalmen, to increase in this way the output of the cabins, and to make it possible moreover, in exceptional cases (great rush of passengers, more or less serious breakdowns in the working) where the ordinary practice has to be modified, to carry out the service under easy and quick conditions.

" In Germany and in Belgium, etc..."

Mr. Weissenbruch. (In French.) — I propose to strike out in the paragraph the following sentence :

" In France, trials are in progress with a view to operating all the points of a route by means of a single lever."

Mr. Gérardin. (In French.) — When one

reads the report, one recognizes that the reporters are not partisans of the route lever. They have given their opinion and if we strike out some of the passages in the conclusions, we should have the appearance of admitting the considerations set forth in the report.

Mr. Descubes. (In French.) — The report does not concern the countries using the German language, and yet both Germany and Belgium are concerned in the conclusions.

Mr. Weissenbruch. (In French.) — As we state in the preamble of the conclusions, we have endeavoured to give a wording which would be acceptable to all countries. We came to an agreement with Mr. Ulbricht.

Mr. Descubes. (In French.) — If that is so, I do not insist.

— The last paragraphs are provisionally adopted.

The President. (In French.) — The definite text of the conclusions will be submitted to you on Monday morning.

We now pass to littera *B*, which runs as follows :

" Littera *B*. — 1° Mechanical and electrical appliances are in use for locking the points during the period while they are being run over by the trains. These arrangements, which should have a length at least equal to that of the greatest distance between the wheel centres of vehicles in use on the railway system, are not generally applied except in the case of points taken facing.

" There is a tendency on the continent to gradually substitute electric treadles for mechanical treadles.

" 2° Electric treadles are generally worked by means of a normally flowing current interrupted by means of a foot-operated economiser switch ; by this means the difficulty of insulation of the points can be easily overcome.

" 3° The arrangements at the end of a route, acting only after the last wheels have passed, enable all the points on a route to be interlocked up to the moment at which the train has entirely cleared the route. The use of these arrangements may be substituted for a series of locking bars at the points with economy."

Mr. Verdeyen. (In French.) — We propose to replace the word " gradually " by " in numerous cases ".

Mr. Tettelin. (In French.) — The tendency to substitute electric treadles for mechanical treadles has not been very marked in France.

Mr. Weissenbruch. (In French.) — There is a very definite tendency, according to the answers which we have received.

Mr. Tettelin. (In French.) — Mr. Jullien, who is prevented from attending this meeting, has asked me to state that the Orleans Railway has for some time been trying a new type of mechanical treadle, 12 metres (39 ft. 4 in.) long, on the Lebeau system.

Mr. Jullien thinks that this treadle, which is not overloaded, is much superior to the electric treadle.

Mr. Weissenbruch. (In French.) — Frequently often have we thought that the

problem was solved, but investigation has proved that this was not the case.

Mr. Tettelin. (In French.) — At the present moment, on the French Northern and on the Orleans, there is a clear tendency in favour of this new mechanical treadle.

Mr. Weissenbruch. (In French.) — During my travels in America, I was everywhere told that one kept to the mechanical treadle. When I remarked that this appliance did not give any safety, I was told that I was mistaken.

Now I find from Mr. Carter's report that all this is changed now and that the electric treadle is quickly spreading over the United States.

Mr. Descubes. (In French.) — On the French Eastern Railway, we have extended the use of electric treadles, although they present a certain danger to which I wish to draw the attention of the section.

The Belgian State Railway, we read in the report, is systematically generalizing the use of electric treadles 15 metres (49 ft. 3 in.) in length, to points taken from the facing side.

That length seems to me short, and for this reason.

When there is a mechanical treadle, this acts at the same time as the bolt unlocking the switch. One can hence no longer affect the position of the switch as soon as a wheel touches the treadle. With the electric treadle, the effect is not the same. For in order to operate the facing switch, one begins by sending an electric current to the treadle; if there is no wheel on that treadle, current returns to the bolt, excites the relay and one can then operate the handle of the lever. Starting from that moment, the lever is free and remains free even if a locomotive reaches the treadle immediately after the unlocking. The signalman can accordingly operate the switch under the train, between the moment that he acts on the handle and the moment he throws over his lever, plus the time the train requires for running the distance from the beginning of the treadle to the nose of the switch. Now a quick train running at 120 kilometres (74·5 miles) per hour does not require half a second to run a distance of 15 metres (49·21 feet). An electric treadle limited to this length can accordingly give false safety, unless the signal interlocked with the switch is quite near to the treadle

The French Eastern Railway has accordingly decided to have electric treadles 24 or 36 metres (78 ft. 8 in. or 118 feet) long, so as to avoid accidents. We even increase this length whenever this is possible.

On the French Eastern Railway the mechanical treadle is raised the moment the switch begins to act and it remains raised during the duration of the movement.

Our stop signal is generally placed 100 mètres (109 yards), sometimes 120 metres (131 yards), in front of the nose of the switch. If that distance was only 20 metres (22 yards) and if all the part in front of the switch was insulated, the occurrence I have described could not happen, because the signalman must have set the signal to danger before touching the switch lever.

I do not assert that this danger is great, but I nevertheless think it advisable to draw the attention of the Congress to a

point which is but little known, and as there is no disadvantage in increasing the length of the insulated rails one should not hesitate to do this.

Mr. Verdeyen. (In French.) — This is the wording proposed by Mr. Motte :

" Electric treadles have been substituted, in many cases, for mechanical treadles."

Mr. Weissenbruch. (In French.) — One might say :

" Electric treadles, the length of which one can easily be increased, have been substituted in many cases for mechanical treadles. "

Mr. Tettelin. (In French.) — I propose to add the words " and usefully " after the word " easily ".

Mr. Descubes. (In French.) — One must not go too much into detail.

Mr. Gérardin. (In French.) — Why does one return to the release of routes? We have already spoken about it in littera *A*. It is the same idea again.

Mr. Weissenbruch. (In French.) — We must take the conclusions of littera *B*.

— Littera *B* is provisionally adopted.

The President. (In French.) — This is littera *C* :

" The use of a graphical method enabling the investigation of the best utilization of tracks serving passenger platforms may be of very great service, particularly in the case of modification of the track arrangement.

" The method used by the Belgian State Railway in particular affords a general and complete solution of this problem. "

Mr. Gérardin. (In French.) — The last sentence seems to me to be useless and I propose that it should be struck out.

Mr. Weissenbruch. (In French.) — We do not object to that.

— Littera *C* is provisionally adopted subject to the sentence in question being struck out.

The President. (In French.) — We have concluded the examination of question X and will fix the definite wording of the conclusions at our meeting of Monday morning.

Communication.

The President. (In French.) — I call upon Mr. Watson to make a communication.

Mr. H. A. Watson, North Eastern Railway, England. — I wish to inform the meeting that the North Eastern Railway has for some time been making trials with an apparatus for repeating on the locomotive the track signals.

This apparatus, which is operated by means of electricity, consists of a brush made of steel wire and hung from the locomotive, which comes in contact with a copper bar placed between the rails, at a suitable height. This bar receives current from the signal. The steel wire brush is used to avoid any risk of breakage. The driver is warned by a bell when he is near the signal, and if this is standing at " danger ", this indication is repeated on the locomotive; if the signal is at " line clear ", this is equally indicated on a locomotive.

The apparatus also shows the driver what road he is to take at junctions.

This apparatus has been used above all on account of the fog which is frequent in November and in December, and it works so well that it has been decided to use it on a large scale.

Up till now it has only been used as auxiliary to the ordinary signals, but trials are being carried out in order to see if it is not possible to eliminate the other signals and only have that in the cab. It remains to be seen whether one can have absolute confidence in the latter.

I may perhaps be allowed to remind you that in England we have two signals, the distant and the home. The former is not absolute, but only gives the driver a preliminary indication; it tells him what the position of the second signal is. If it stands at " danger ", the driver knows that he must stop at the home signal.

The trials mentioned were carried out on locomotives hauling the fastest trains on this railway.

A similar apparatus is being tried on the Great Western Railway.

I invite the members of the Congress who come to England to see the good results obtained with this appliance, and I will be very pleased to show them how it works. (*Hear, hear!*)

The President. (In French.) — I think I express the feeling of the section in thanking Mr. Watson for his interesting communication.

Meeting held 11 July 1910 (morning).

The President. (In French.) — I call upon Mr. Weissenbruch to read the text of the conclusions drafted by agreement among the different reporters.

Mr. Weissenbruch, *reporter.* (In French.) — The following is the first paragraph, littera *A*, of the proposed conclusion :

" Although hand-operated apparatus are by far the most common and as a rule give satisfaction, the use of fluid-operated central apparatus has made rapid progress during the last ten years or so, particularly at very large stations. It has the advantage of allowing of greater concentration, and, consequently, of greater rapidity of operation, and, in some cases, of greater safety, while at the same time facilitating the work of the employees. It makes it at the same time possible to obtain very complete safety by arranging for the clearing of routes by the train, by indicating the true position of the points, by obtaining the return-to-stop position of the signals after the passage of the train, or in case of any disturbance in the route prepared, etc."

The new wording does not differ much from that provisionally adopted at the last meeting. There is a mere inversion of the terms " greater rapidity " and " greater safety ", so that one could not draw from the text a conclusion which is far from our thoughts.

On the other hand, apart from some trifling modifications, there are only the

words " in the route prepared " instead of " in the route run over ", in order to make matters clearer.

Mr. Descubes. (In French.) — I have just read through the text of the conclusion and I find that in spite of our efforts we have obtained no satisfaction as regards route-lever apparatus.

In fact the proposed conclusions imply that in case of break-downs the route lever does not give as much safety as the other devices.

Mr. Weissenbruch. (In French.) — It is now only a question of drafting and we are quite ready to modify the text and to indicate the reasons why in other countries one has not yet had recourse to the route lever. That, however, does not say that they will not use it in the future.

We were also told yesterday that there are now new apparatus which made it possible to obtain both the advantages of the route lever and those of the individual lever. It is clear that the conclusions do not apply to this.

Mr. Descubes. (In French.) — We shall in the end come to an understanding, but I repeat that the text as submitted to us implies that the route lever does not make regular operation possible if a switch is out of order. That is in complete contradiction with what we have said.

I am much surprised at this contradiction by the reporters who belong to a country where trials have not been made with the apparatus recommended by the French engineers.

Mr. Weissenbruch just said that there were new apparatus which made it possible to obtain at the same time the advantages of the route lever and those of the individual lever. I do not wish to enter into these details, for if it was necessary to discuss, even summarily, the motors and examine them one after the other, we would never come to an end. Some prefer the Siemens & Halske system, others the Siemens Brothers system, other again the Westinghouse system.

The point involves a question of principle.

As regards the report, it was unfortunately distributed under conditions which were unusual and contrary to custom.

Mr. Weissenbruch. (In French.) — I must protest. That is quite a mistake. Many other reports have had the same fate.

Mr. Descubes. (In French.) — I can but regret it.

However, that may be, the report must not be a piece of special pleading, traces of which are left in the conclusions.

We propose conclusions which are very moderate and are in a form containing no reflection upon anyone. I ask that they should be printed like the others.

Mr. Weissenbruch. (In French.) — Allow me to reply in two words to Mr. Descubes who asks that his proposals should be printed and distributed before they are discussed. I do not oppose this, but I must remark that this is not customary. The proposals of Mr. Descubes, if he so desires, will find their place in the report of the section.

My honourable colleague has also stated that our report was distributed under conditions which were contrary to rule.

Mr. Descubes. (In French.) — Under

conditions which were contrary to custom.

Mr. Weissenbruch. (In French.) — That is a complete mistake. For as I have already remarked when I answered Mr. Heurteau, similar cases of delay have occurred at every session. Messrs. Auvert and Mazen's report about electric traction was distributed at the Paris session in 1900 at a moment when the discussions had already commenced.

There have always been reporters who have been late and we have not been the only ones.

We cannot be reproached as having set an example to our colleagues who were as late as we were.

However, that may be, it is simply a question of coming to an understanding and to give an indication in the conclusions of the opinions which have been given during the discussion. Now Mr. Descubes proposes to introduce a paragraph describing the advantages of the route lever such as devised in the different systems of the French engineers. He also indicates the reasons why these engineers have with much ingenuity and cleverness, combined their apparatus.

As for us, we have limited ourselves to giving the reasons why this scheme has not been followed either in Belgium or in England or even in Germany.

I repeat, if our wording seems to you to be too absolute, we are ready to tone it down in order to show our wish for conciliation. I am, however, of opinion that our text contains nothing of a kind to be disagreeable to you.

Mr. Gérardin. (In French.) — What has complicated the situation, is the argument developped in Messrs. Weissenbruch and Verdeyen's report, and they have really expressed a personal opinion.

When we, Frenchmen, had read the report, we came to the conclusion that there was a desire to condemn the idea of the route lever. One reads, in fact, in that report that several French companies had again taken up the trials made in Germany in 1895 and given up since.

Under these conditions, we thought that we must leave no trace, in the conclusions, of what seemed to be implied by the report and that an idea which seemed practicable should not be condemned.

If the section would make a reservation of some kind, for instance say that it does not accept the argument set forth in the report, we could simplify the conclusions very much.

We admit that Belgium and Germany are not partisans of our route lever which is however in our opinion the solution of the future; but we ask that the conclusions should be preceded by the following words : " The section makes every reservation as regards the arguments set forth in the report ".

Mr. Weissenbruch. (In French.) — It is not necessary to say that the section makes reservations as regards the arguments set forth in the report, as the latter always reflects the personal opinion of the reporter and is binding only on him. The Congress is only responsible for its own conclusions.

If stress is laid on it, we will say that the report is the personal work of the reporters. That is however useless, as the word " section " must disappear after the decision at the general meeting. What we

*

are preparing is only a set of proposed conclusions to be submitted to that meeting.

Mr. Descubes. (In French.) — The new wording of Messrs. Weissenbruch and Verdeyen's conclusions should be printed.

There are in fact many delegates present who are not as familiar with the subject as the reporters. One must at least have time to consider the words in order to be able to answer them, and this is difficult if they are merely read out.

Mr. Weissenbruch. (In French.) — We have no objection to the printing of the new text, so that everybody can examine it at leisure. We will accordingly take the measures necessary.

In order to save time, we might appoint a committee to draw up a text of a kind to satisfy everybody.

Mr. Descubes. (In French.) — Quite so, that is a good suggestion.

The President. (In French.) — That committee could meet at once and I propose that it should consist of the members of bureau and the reporters, together with Messrs. Tettelin, Descubes, Gérardin and Jullien. (*Approval.*)

Meeting held 11 July, 1910 (afternoon).

The President. (In German.) — Mr. Ulbricht proposes to bring forward a small correction in connection with the discussion of question X and proposes that it should be entered in the minutes. You will accordingly allow me to call upon him to speak. We will then pass to the discussion of the new proposed conclusions.

Mr. Ulbricht, *reporter.* (In German.) — At the last meeting, a Russian delegate remarked that my report did not devote enough attention to the installations used in Russia in many cases. He added that this was probably due to the Russian administrations having sent answers in late. I had an interview on this subject with the Russian delegates and I observed that the information in question had not reached me and hence could not be taken into consideration in my report. I wished to make this remark in order that it might not be thought that I had not sufficiently utilized, in my report, the information supplied.

The President. (In German.) — We will note Mr. Ulbricht's remark in the minutes.

I propose to pass now to the consideration of the definite conclusions drafted by the committee appointed this morning.

If everybody agrees, I will ask Mr. Weissenbruch to tell us the result of the deliberations of that committee.

Mr. Weissenbruch, *reporter.* (In French.) — " Littera *A*. — Although hand-operated apparatus are by far the most common and as a rule give satisfaction, the use of fluid-operated central apparatus has made rapid progress during the last ten years or so, particularly at very large stations. It

has the advantage of allowing of greater concentration, and, consequently, of greater rapidity of operation, and, in some cases, of greater safety, while at the same time facilitating the work of the employees. It makes it at the same time possible to obtain very complete safety by arranging for the clearing of routes by the train, by indicating the true position of the points, by obtaining the return-to-stop position of the signals after the passage of the train, or in case of any disturbance in the route prepared, etc.

" The methods of power supply used are electric current, compressed air with electric indicaling gear, and water under pressure. Purely electric, and electro-pneumatic installations are at present the more usual.

" In the case of isolated appliances, carbonic acid has been used with success.

" In very large stations, the concentration makes it possible to effect a saving by a reduction in the number of signalmen.

" In France, during the last few years, important applications have been made of apparatus with route levers. The end in view appears to have been attained under favourable conditions.

" In other countries at present no attempts are made to operate points simultaneously, other than those usually worked in combination for a cross-over; up to the present, the apparatus so designed seems to satisfy practical requirements.

" Both systems are good; but it is advisable to wait for further experience as to the advantages and disadvantages of these two systems.

" Central electric installations are operated by direct current. Single-phase current and three-phase current have also been used. Up to the present, some difficulties have been met with, among others the impossibility of utilizing accumulators as a reserve."

Mr. Tondelier suggests to me that it would be better, at the end of the seventh paragraph, to replace the words " of these two systems " by the words " of each of them."

This would evidently be better from the point of view of style.

Mr. Descubes. (In French.) — I agree.

Mr. d'Abramson. (In German.) — Just a few words about littera *A*. The sixth paragraph says : " In other countries at present... ". That seems not to be quite correct. In Russia, for instance, both the French system and the German-Belgian system are used. It would perhaps be better to say : " In most of the other countries at present..."

Mr. Weissenbruch. (In French.) — The text runs : " In other countries at present..."

Mr. d'Abramson asks that we should say : " In most of the other countries at present..."

I see no objection to the adoption of this amendment.

— Littera *A* is adopted as amended by Messrs. Tondelier and d'Abramson.

Mr. Weissenbruch. (In French.) — Here is littera *B*, as proposed by the special committee :

" Littera *B*. — Mechanical and electrical appliances are in use for locking the points while they are being run over

by trains. These arrangements, which should have a length at least equal to the greatest distance between axles, are not generally applied except in the case of points taken facing.

" On the Continent electric treadles, which can easily be made longer, have frequently been substituted for mechanical treadles.

" 2. Electric treadles are generally worked by means of a normally flowing current (' *courant de repos* ') interrupted by an economizer switch (' *contact d'économie* ').

" The points can be insulated without material difficulty.

" 3. The arrangements acting only after the last wheels have passed, enable all the points on a route to be interlocked up to the moment at which the train has entirely cleared the route. The use of these arrangements may be substituted for a series of locking bars at the points with economy."

The figures 2 and 3 which are in front of the third and fifth paragraphs should be struck out. (*Approval.*)

Mr. Descubes. (In French.) — A remark is made to me which is correct enough from the point of view of the French wording.

The third paragraph runs :

" Electric treadles are generally worked by means of a normally flowing current (' *courant de repos* ') interrupted by an economizer switch (' *contact d'économie* ')."

Clearly we all know what is meant by " *courant de repos* ", but it is not very correct.

Mr. Weissenbruch. (In French.) — It is a technical expression which I have found in a French book.

Mr. Descubes. (In French.) — It is however not used in France. The same applies to " *contact d'économie* ".

Mr. Weissenbruch. (In French.) — A " *courant de repos* " is a current which flows when the apparatus is at rest. If we were to say " *courant continu* " one would think that the apparatus was always at work.

Mr. Descubes. (In French.) — We always have an appliance for stopping the current whenever it is not required.

Mr. Weissenbruch. (In French.) — The German wording is clearer.

Mr. Descubes. (In French.) — Please note that we are really in perfect agreement.

I propose to adopt the following wording : " Electric treadles are generally worked so that the points are released by the flow of the current. The circuit is normally interrupted by an economizer switch."

Mr. Tondelier, *vice-president.* (In French.) — The fifth paragraph states :

" The arrangements acting only after the last wheels have passed, enable all the points on a route to be interlocked up to the moment at which the train has entirely cleared the route."

Now the interlocking is produced after the passage of the first axle and the unlocking after the passage of the last axle. That idea should be expressed in another way.

I accordingly propose that we should say ;

" Arrangements acting only after the last axle has passed, enable all the points on a route to be interlocked, from the moment the first axle has reached it till the moment the last axle has left it."

— Adopted.

— Littera *B* is adopted as amended by Messrs. Descubes and Tondelier.

Mr. Weissenbruch. (In French.) — Here is littera *C* :

" Littera *C*. — The use of a graphical method enabling the investigation of tracks at large passenger stations may be of very great service, particularly in the case of modification of the station arrangements."

— Adopted.

Communication.

The President. (In French.) — I call upon Mr. Weissenbruch.

Mr. Weissenbruch. (In French.) — Gentlemen, for several years the Belgian State Railway has made repeated trials in order to work out an appliance for warning the driver, in times of fog, of the position of the signals.

The first idea, due to Mr. Ramaeckers who was then general manager of the Belgian State Railway, consisted of warning the driver by audible signals placed along the track.

After rather long experiments with bell apparatus, which as might be expected gave negative results, we thought that detonators formed of a sporting cartridge and placed not on the rail, but to the side of it, would be able to give some warning to the driver.

We accordingly made trials with a device due to a French inventor, Mr. Cousin ; we placed them on the Brussels-Mons line 100 metres (109 yards) in front of the signal concerned, but we have not yet been able to find out how they work because there has been no fog since they were put in place.

This question is closely connected with that of the transformation of the signalling system by the adoption of a distant signal which may be passed when it stands at " danger ".

The Belgian railways still have, as a general rule, an " absolute stop " distant signal. They had decided to effect the change on the Brussels-Mons line, but this alteration has been postponed for reasons independent of the choice of the apparatus and it was found that the Brussels-Antwerp line had first to be altered. As the manufacturer could not supply the Cousin apparatus for this line sufficiently soon, we sought other devices.

At that time, there were several luminous repeating signals on trial at the entrance to Antwerp. We had the idea of making trials with these signals on a larger scale and we succeeded perfectly. A description of this system is given in the October number, 1909, of the *Bulletin of the Railway Congress*.

The lamps, three in number in front of the warning distant signal and two in number in front of the absolute stop signal, are placed at the level of the eye of the driver, and show changing colours, yellow and green ; yellow to indicate " stop further on " and green to indicate " line clear ".

The system gave perfectly satisfactory results during last winter, when there was much fog. The fast trains between Brussels and Antwerp were able to run as in ordinary weather.

We have, however, not finally adopted this device. We are still making experiments with an apparatus placed on the locomotive. This cab signal was devised by a Belgian inventor, Mr. César. It works by means of an electric current generated by a battery situated on the engine and short-circuited by a " crocodile ". The " danger " signal and the " line clear " signal are clearly indicated to the driver in the cab by an indicator and by sounding a compressed-air whistle.

We are going to make trials on the larger scale, on the Schaerbeck-Louvain-Liége line.

There is however an objection to this system.

It is feared that placing these devices on the locomotives — and Mr. d'Abramson also expresses this fear — will divert in time the attention of the driver from the track.

It is in order to counteract this disadvantage that in Russia the repeating signals are only used in times of fog. In order to meet this objection, it has been proposed to give notice on the locomotive only of the approach to the signal without indicating whether it is at " line clear " or at " danger ". I think experiments of this kind have recently been made in Germany.

The Snyers apparatus has been designed to satisfy this condition, and we have decided to try it. Its working depends on the mechanical action, on the locomotive, of a brush made with long steel wire, placed on the track.

To sum up, we have made numerous experiments, but we have not yet adopted a definite solution.

Mr. Descubes. (In French.) — As the point which Mr. Weissenbruch has just raised has turned up unexpectedly, I have not been able to bring the necessary papers and to deal with it in my turn. I will accordingly limit myself to giving some summary information.

Several years ago the French Eastern Railway placed a Cousin apparatus at a point near the Paris station, where the line used by the trains coming from the Ardennes and from Strasburg and the line used by the trains going to Mulhouse cross each other at a level. This crossing being frequently used, we have duplicated the distant signal by an extra warning signal.

For this purpose, we put in a Cousin detonator placing machine which until now has given us every satisfaction. It is a good apparatus, which up till now has given rise to no failure...

Mr. Weissenbruch. (In French.) — It is a very well-made machine.

Mr. Descubes. (In French.) — ... But it has the disadvantage of being very dear.

As regards the repetition of signals on the locomotive, we have tried, on the one hand, the Marin apparatus, on the other, the " crocodile " of the French Northern Railway, modifying it however quite appreciably. For two years we have been making experiments with this apparatus in the Ardennes, where fogs are rather frequent.

In this investigation, we have taken as our programme not only the operation of

an audible signal placed on the locomotive and acting when the disk signal in standing at " danger ", but also the recording, on the Flaman indicator, of the position of the signal, whether it stands at " danger " or " line clear ". One can ascertain in this way whether there have been too many failures of the appliance. These trials have given good results and failures have been comparatively rare. There are however still a certain number of failures, particularly when there is hoar frost and we have asked ourselves whether it is not advisable to have two brushes to each " crocodile ", one for removing the hoar frost and the other for the current. In a few months we are going to try gridiron " crocodiles ".

Mr. Weissenbruch said a little time ago that the Belgian railways intended to use the crocodile in times of fog only. I think as he does that from the point of view of the education and the strength of mind of the driver, it would be well to leave him in ignorance of the moment this device is set in action, so as not to dull his attention. However I doubt very much whether the State authorities will allow this. When we have started using the crocodiles in times of fog, six months will not elapse before we receive the order to use them always.

Mr. Weissenbruch. (In French.) — It is in order to meet this objection that the device on the locomotive should only show the proximity of the signal, but not whether it is standing at " danger " or at " line clear ". The signal on the locomotive will not tell the driver whether he can go on or whether he must stop, it will only tell him to pay attention.

Mr. Descubes. (In French.) — But we shall nevertheless be compelled to use it always.

It is certain that in the case of the Villepreux accident which occurred between 6 and 7 p. m. when the signal was still visible from a long way off, it is certain, I say, that if one had had crocodiles and had not had them in use the day the accident occurred, there would have been a general outcry against the administration. That is a side of the question which must not be lost sight of.

As for me, I am of opinion that we must all continue our investigations with the sincere desire of succeeding. We must not generalize the use of any given appliance before we have arrived at perfectly satisfactory results.

Mr. Weissenbruch. (In French) — What do you think of the solution which would consist of warning the driver of the proximity of the signal? How would the public receive this idea?

Mr. Descubes. (In French.) — I think it would be useful, in certain cases, to warn the driver of the proximity of a signal, even in clear weather. In fact when a signal is seen against a hill with woods and fields, it is seen with difficulty at certain hours of the day.

In order to draw the attention of the driver to the proximity of the signal, we have had some telegraph posts with rings which are alternately red and white.

Mr. Weissenbruch. (In French.) — We have applied a similar idea...

Mr. Dufour. (In French.) — The same in Holland. We have placed some boards, painted white, near the signal.

Mr. Weissenbruch. (In French.) — ... on the Belgian railways.

We have placed before the distant signal a series of five horizontal planks slightly inclined relatively to the axis of the track. The drivers are delighted with this arrangement which, I am personally convinced, will suffice to attract their attention.

These boards, placed at distances of 50 metres (55 yards) from each other, are marked with stripes and numbered in their order from the signal, so that if a driver suddenly perceives No. 3, he has only two more to pass.

Mr. Descubes. (In French.) — That is a continuous warning.

Mr. Weissenbruch. (In French.) — I have proposed this system and described it in the *Bulletin of the Congress* (1).

A delegate. (In French.) — Is this device such that it is of use at night?

Mr. Weissenbruch. (In French.) — Certainly; these boards are seen very well at night. The head light of the locomotive lights them up, as they are near the track.

A delegate. (In French.) — Some day you will be compelled to light them up.

Mr. Weissenbruch. (In French.) — We have made some very interesting trials in the way of replacing these boards by slightly-curved enamelled plates which are very visible at night. At first sight one does not believe this possible, but the evidence of the experiments is conclusive. The drivers are well satisfied with this installation.

(1) See *Bulletin of the Railway Congress*, November, 1902, p. 912.

Mr. Descubes. (In French.) — It is understood, of course, that the warning signal on the locomotive acts, whether the signal stands at " danger " or at " line clear ".

Mr. Weissenbruch. (In French.) — Certainly.

Mr. Dufour. (In French.) — In Holland, the Dutch State Railway has placed on some lines, before the home signals, at a distance of 850 metres (930 yards), warnings consisting of three boards about 5 metres (16 ft. 5 in.) long. These boards are painted white, are gently inclined and are placed about 10 metres (11 yards) apart at a height above rail-level, which increases from 1·50 to 3 metres (4 ft. 11 in. to 9 ft. 10 in.)...

Mr. Weissenbruch. (In French.) — We place them at the height of the head light.

Mr. Dufour. (In French.) — ... but the drivers say they do not see them.

Mr. Weissenbruch. (In French.) — That, I think, is because the height of those boards goes on increasing. Our experiments have shown that they should be placed at the height of the head light of the locomotive.

Mr. Maison. (In French.) — It is feared that a repeating signal placed on the locomotive will finish by dulling the vigilance of the driver. Differences of opinion may exist about a question of this kind.

I think however that I must remark that the railway industry is not the only one in which the use of automatic devices for compensating for any want of attention of the employees has been considered. A

case may be found in the mining industry, for instance where for a long time automatic stops have been provided at the pit heads in order to prevent any overwinding in the case of want of attention of the employee in charge. These installations have not dulled the attention of the employees and have eliminated a serious cause of accidents. One does not see why the same should not be the case with appliances for repeating the signals on the locomotives.

It seems very necessary, in my opinion, taking the present state of railway operation into consideration, to have appliances on the locomotives to show the drivers the position of the signals. It is because as a matter of fact, during the last few years, the conditions under which trains run have become modified. The locomotives, which have become more powerful, have become larger, and the driver is placed in a less favourable position to observe the signals from a distance. Moreover, speeds have increased materially. A very ordinary speed is 30 metres (98·43 feet) per second. Ten seconds are required for 300 metres (328 yards); that is often the whole distance over which a signal can be seen. Then a moment of inattention of the driver, a momentary neglect, any occurrence on the locomotive distracting the attention of the driver for a few moments, suffice, in case of an unfortunate coincidence, to keep the driver from seeing the signal, and a serious accident may occur.

Accordingly I think, in spite of the objections of principle frequently raised against devices for repeating signals, that safety will be materially increased by the use of these devices not only in times of fog, but also in clear weather, that is to say, if they are taken into ordinary everyday use.

Mr. Weissenbruch. (In French.) — If a warning device is placed on the locomotive in accordance with the idea we have just been discussing, the driver will be warned of an approaching signal and hence he would be obliged to notice it; if necessary a device can be added to check whether the driver has been warned or not.

The President. (In French.) — The remarks just exchanged are very interesting. They will be reproduced in the verbatim report.

DISCUSSION AT THE GENERAL MEETING

Meeting held on 16 July, 1910 (morning).

MR. P. WEISSENBACH, PRESIDENT, IN THE CHAIR.

GENERAL SECRETARY : MR. L. WEISSENBRUCH.

FIRST ASSISTANT GENERAL SECRETARY : MR. MÜRSET.

SECOND ASSISTANT GENERAL SECRETARY : DR. A. BONZON.

Mr. Kareischa, *principal secretary of the 3rd section*, read, the

Report of the 3rd section.

(See *Journal de la huitième session*, No. 11, p. 7.)

" The reporters, Messrs. DUFOUR, ULBRICHT and VERDEYEN, gave a summary of their report. Mr. Carter, reporter for America, was not present.

" On the proposal of Messrs. JULLIEN (*Orleans Railway*) and VERDEYEN, it was decided not to discuss hand-operated apparatus. The Permanent Commission was requested to insert this interesting question among the agenda for the next session of the Congress. It was then agreed to take as basis for the discussion, the conclusions proposed by Messrs. Weissenbruch and Verdeyen, which were drafted in such a way as to include the whole of the question, and to which Dr. Ulbricht agreed subject to some modifications in the wording.

" MR. ULBRICHT had recently received some supplementary information from the Swedish State Railway in answer to question 16 of the detailed list of questions contained in his report. This information would be inserted as an appendix to the verbatim report of the discussion.

" Mr. MAAS-GEESTERANUS (*Dutch Railway Company*) gave some information on the electric and electro-pneumatic apparatus in use in Holland. He stated that he had made some very satisfactory experiments with the latter.

" MR. PETRI (*German government*) drew attention to question 59 of Mr. Ulbricht's reports, referring to the question of warning the driver, independently of the signals. He desired to know what experiments had been made on this point in other countries.

" Mr. D'ABRAMSON (*Russian State Railway*). In reply stated that an apparatus for repeating on the locomotive the track signals had been in use on the Russian South Western Railway during the last few years. But it was only used on exceptional occasions (thick fog, snow, etc.), so as not to dull the attention of the drivers. The apparatus gave good results.

" Mr. WEISSENBRUCH (*reporter*) observed that Mr. Ulbricht had dealt with this question because the reporters had always been given the greatest liberty in widening the scope of any question. He himself, and also Mr. Carter, had not given such a wide interpretation to the question. He was however ready to give some information on the subject, if the President thought this desirable.

" Mr. ULBRICHT suggested that this important point might form the subject of an exchange of opinions.

" Mr. PETRI also urged that some information should be given on this point.

" THE PRESIDENT proposed to postpone this till after discussion of littera C of the conclusions.

" Mr. DESCUBES (*French Eastern Railway*) then addressed the section. He thought that Messrs. Weissenbruch and Verdeyen's report criticized the route apparatus very severely, the more so as these apparatus, which were in use only in France, were mostly not sufficiently well known to the reporters. It was incorrect that the French engineers had repeated the trials made in Germany fifteen years ago; their work had been absolutely original. The term " recent trials " could also not be applied to systems which had shown what they were capable of at Valenciennes, at Nancy and at Bordeaux, and at the last station during seven years already. According to the report, it would seem that the Bordeaux apparatus had been copied from an apparatus patented by the firm Siemens and Halske, and this the reporters could certainly not have meant; now Mr. Bleynie had obtained for his apparatus a patent in Germany.

" The French engineers had above all tried to increase the capacity of the cabins, to simplify the operation and to facilitate the work of the signal-men under all conditions; the possibility, in case of a strike, of letting the first-comer operate the levers was only an additional advantage.

" Mr. Descubes also remarked that the apprenticeship at the ordinary signal-cabins was not so negligible, as the reporters themselves estimated it at two or four weeks. Now at Nancy, not even a whole day was necessary before the signal-men thoroughly understood the operations and were able to increase the station output.

" In case of failure, the cutting-out of one appliance could be effected without hindering the service or reducing the safety.

" As far as the saving of time was concerned, this was by no means illusory. Mr. Descubes quoted some figures in support of this and remarked that in cabins with separate levers and route interlocking, all the levers corresponding to the switches concerned had to be operated in addition.

" The objection raised in France, that the route levers prolonged the time needed for operation, also applied to all the appa-

ratus (German or Belgian) in which route-completing treadles were used; this disadvantage could however be remedied.

" As regarded cost of working, this was about the same as regarded maintenance and supply of power, whether route levers or separate levers were used; but in the case of large signal-cabins it was possible in certain cases to reduce the cost of staff with the first system. Thus in the case of a signal cabin on the French Eastern Railway, now under consideration, 187 levers would be required in the case of a Saxby frame; Mr. Descubes thought that with the newer apparatus in use in Belgium, 265 levers or handles would be necessary; with the Nancy system, 64 levers would suffice.

" Messrs. Weissenbruch and Verdeyen could not admit that their report " criticized very severely " the French apparatus. In recalling the trials made in Germany in 1895, and given up, they only intended to quote history and evidently had not desired to dispute the originality of the French apparatus. What they said about the Bleynie system was only a summary of a passage in the note describing the Antwerp installation, published in 1904 in the *Bulletin of the Congress*.

" The term " recent trials ", to which Mr. Descubes took exception, occurred on page 172 of the offprint (1), in the second paragraph. It referred, if one compared it with the last paragraph of the preceding page, solely to the Descubes system, at Nancy, and to the M. D. M. apparatus experimentally installed at the Paris station of the French Northern Railway.

(1) See also the *Bulletin of the Railway Congress*, No. of August-September-October, 1910, p. 3439.

" The reporters who had been to see the Bordeaux (Bleynie) apparatus in 1909 and the Paris-Nord (M. D. M.) apparatus in 1910, found the same advantages in separate electric levers without the complicated construction which resulted from operation by a single lever.

" The apprenticeship of the signalmen at Alost had been as short as at Nancy. They had been taught, in advance, the plan of the station, the location of the switches and how these were numbered. But it had not been possible for them to enter the cabin till twenty-four hours before it was taken into use; nevertheless there had been no case of delay of any train.

" In case of a break-down of a switch operated separately, the regular operation of the central apparatus could be continued and the mechanical interlocking in the cabin continued to be in action. In exceptional cases one could even refrain from using any special safety appliance.

" The last and quite recent type of route-lever apparatus, the M. D. M. exhibited at Brussels, where devices were used making separate operation possible normally, seemed no longer liable to this objection.

" In order to appreciate the difference of output of the two systems, two identical instances had to be taken. In this case, the difference was reduced to the time necessary for operating the switch levers, a time of but little importance when each of these levers was operated in one operation.

" As for Mr. Descubes's statement, that 187 Saxby levers, which could be replaced by 64 Descubes levers, would require 265 levers or handles with the apparatus in use in Belgium, the reporters could affirm with certainty that they would be

able to reduce this figure of 265 very materially by utilizing all the resources of the Belgian system. In the applications made in Belgium, they had also succeeded in reducing the number of electric levers as compared with the number of Saxby levers. At Alost, 144 electric levers did the work of 381 Saxby levers.

" Mr. HEURTEAU (*Orleans Railway*) regretted that Messrs. Weissenbruch and Verdeyen's report had not been distributed earlier and that Mr. Bleynie had not been able to answer it and eventually be present at the meeting.

" Mr. WEISSENBRUCH also regretted his inability to issue his report sooner. As he had already mentioned, what he had said about Mr. Bleynie's system he had already published six years ago in the *Bulletin of the Congress*. Other reports had also been late and the secretarial offices of the Congress had given them priority. The same thing had happened at other sessions. At Paris, in 1900, Mr. Auvert's report had only arrived after the opening of the session.

" Mr. TETTELIN (*French Northern Railway*) remarked that the reporters themselves admitted that the route-lever system was not inferior to the Belgian or German system. The fundamental idea of the route-lever appeared to be misunderstood, and the separate lever was only a stage in arriving at it. The new apparatus in actual use on the French Northern Railway gave every satisfaction and it was to be regretted that Messrs. Weissenbruch and Verdeyen's report contained remarks which cast doubts on the future of that system.

" Mr. Tettelin laid a description of the new apparatus on the table.

" The REPORTERS took note of Mr. Tettelin's statement that the new apparatus did not exist when they drew up their report; their remarks therefore did not apply to this apparatus which it would be a pleasure for them to examine.

" Mr. JULLIEN asked that the hydro-dynamic apparatus which had been used for the last twenty years on the Orleans Railway, without break-downs, should also be mentioned in the conclusions, and that one should not at once give preference, over the electro-pneumatic apparatus, to the purely electrical apparatus. He did not notice, as clearly as Messrs. Weissenbruch and Verdeyen, any marked preference in the American report in favour of electrical apparatus.

" Mr. DMITRENKO (*Russian State Railway*) stated that in Russia the Bianchi-Servettaz system had been used with success, in spite of the great variations in the temperature, which might amount to as much as 75° C. (135° Fahr.); and sometimes the minimum temperature was 35° C. below zero (—31° Fahr.). On the other hand, good results had not been obtained with apparatus using liquid carbonic acid.

" Mr. SEGRÈ (*Italian State Railway*) supported Mr. Jullien's conclusions and stated that in Italy the principle of the hydro-dynamic apparatus had also been applied since, and that with success.

" Messrs. ULBRICHT, DUFOUR and JULLIEN proposed some further modifications in the wording of the proposed conclusions, and Mr. VERDEYEN read revised conclusions

amended in accordance with the results of the discussion. Messrs. Gérardin (*French Eastern Railway*) and Jullien had assisted in this revision.

" As regarded littera *B*, Mr. Tettelin, acting for Mr. Jullien, made a communication on the subject of a new mechanical locking treadle, 12 metres (39 ft. 4 in.) long, which had been tried on the Orleans Railway during the last few months; it worked very smoothly and appeared to be giving excellent results.

" Mr. Descubes stated that the electric locking treadle was frequently used on the French Eastern Railway; he mentioned however that in certain cases it was necessary to increase the length of these devices to 36 metres (118 feet), and this could be done without difficulty with electricity.

" Mr. Verdeyen (*reporter*) then read the conclusions referring to littera *B* and to littera *C*. Messrs. Descubes and Motte (*Belgian State Railway*) supported the modifications in the wording, which had been proposed in agreement with Mr. Ulbricht.

" Mr. H. A. Watson (*North Eastern Railway, England*) mentioned an interesting apparatus which was being tried on the North Eastern Railway for repeating in the engine cab the track signals. He invited any members of the Congress to come to England to see the good results obtained with this apparatus and expressed his readiness to show them how it worked.

" Mr. Weissenbruch (*reporter*) gave a short account of the experiments made in Belgium with warning appliances on the track and on locomotives, to be used in cases of fog. After having experimented without success with bells, the administration of the Belgian State Railway decided on making a trial, on the large scale, of Cousin's detonating apparatus, placed on the track 100 metres (109 yards) in advance of the distant signal to be passed. The apparatus were in place, but there had not yet been any fog. Another trial had been made between Brussels and Antwerp; an account of it had been published in the *Bulletin of the Congress* for October 1909. Five lamps were placed at the height of the eye of the driver; particulars were given in the appendix to Mr. Motte's report (1) on subject III (junctions). The results were excellent. Means for making such installations under economical conditions which would allow their extended application were now being investigated. Finally it had just been decided to try between Schaerbeek and Liége the César locomotive-cab apparatus, which indicated the " line clear " and " danger " positions of the signal electrically by means of a kind of treadle.

" It was also under consideration to try apparatus which merely warned the driver that he was approaching the signal, in order not to distract his attention from the track, which should be his chief duty.

" To sum the matter up, the Belgian State Railway was not yet in a position to recommend any definite solution.

" Mr. Descubes gave some information about the trials made by the French Eastern Railway for the last two years. The position of the signals, whether off

(1) See *Bulletin of the Railway Congress*, March, 1910, p. 1271.

or on, was marked on the tape of the Flaman recorder, and one could detect all failures with certainty. The number of the latter was by no means negligible, particularly in winter, and it was advisable to wait till one had obtained more satisfactory results, before adopting any apparatus generally.

" After some more remarks, especially by Mr. TONDELIER (*Belgian State Railway*), the following conclusions were adopted for submission to the general meeting."

The President. (In French.) — The following are the

CONCLUSIONS.

LITTERA *A*.

" Although hand-operated apparatus " are by far the most common and as a " rule give satisfaction, the use of fluid- " operated central apparatus has made " rapid progress during the last ten years " or so, particularly at very large stations. " It has the advantage of allowing of " greater concentration, and, consequent- " ly, of greater rapidity of operation, and, " in some cases, of greater safety, while " at the same time facilitating the work of " the employees. It makes it at the same " time possible to obtain very complete " safety by arranging for the clearing of " routes by the train, by indicating the " true position of the points, by obtaining " the return-to-stop position of the signals " after the passage of the train, or in case " of any disturbance in the route pre- " pared, etc.

" The methods of power supply used " are electric current, compressed air " with electric indicating gear, and water " under pressure. Purely electric, and " electro-pneumatic installations are at " present the more usual.

" In the case of isolated appliances, " carbonic acid has been used with suc- " cess.

" In very large stations, the concentra- " tion makes it possible to effect a saving " by a reduction in the number of signal- " men.

" In France, during the last few years, " important applications have been made " of apparatus with route levers. The end " in view appears to have been attained " under favourable conditions.

" In most of the other countries at " present no attempts are made to operate " points simultaneously, other than those " usually worked in combination for a " cross-over; up to the present the appa- " ratus so designed seems to satisfy prac- " tical requirements.

" Both systems are good; but it is " advisable to wait for further experience " as to the advantages and disadvantages " of each of them.

" Central electric installations are oper- " ated by direct current. Single-phase " current and three-phase current have " also been used. Up to the present some " difficulties have been met with, among " others the impossibility of utilizing " accumulators as a reserve."

LITTERA *B*.

" Mechanical and electrical appliances " are in use for locking the points while " they are being run over by trains. These " arrangements, which should have a " length at least equal to the greatest " distance between axles, are not generally

" applied except in the case of points " taken facing.

" On the Continent electric treadles, " which can easily be made longer, have " frequently been substituted for me- " chanical treadles.

" Electric treadles are generally worked " so that the points are released by the " flow of the current. The circuit is nor- " mally interrupted by an economizer " switch.

" The points can be insulated without " material difficulty.

" Arrangements acting only after the " last axle has passed, enable all the " points on a route to be interlocked, " from the moment the first axle has " reached it till the moment the last axle " has left it. These arrangements may in " many cases be substituted, with econ- " omy, for a series of locking bars at the " points."

LITTERA *C.*

" The use of a graphical method ena- " bling the investigation of tracks at large " passenger stations may be of very great " service, particularly in the case of modi- " fication of the station arrangements."

— These conclusions were confirmed by the general meeting.

APPENDICES

APPENDIX I

[656 .257 & 656 .21 (01] —

Note of the administration of the Swedish State Railway in answer to question 16 of the list of questions of Mr. Ulbricht, author of report No. 1.

Our answer to question 16 of the list of questions relating to the operation of switches and signals having been mistranslated, we have the honour of stating it precisely in the lines which follow, leaving it to you to use them, as you may see fit, at the next session of the Congress at Berne.

This question runs as follows : *Have you any arrangements on your systems in which a given position of the switch lever releases the switch, so that it can be operated locally?*

In answering that we use apparatus of this kind rather extensively, we wished to say that provision is made that the switch can be operated locally when the switch-lever is in the *normal position* or in the *thrown-over position*, but not, as stated on page 42 of the report (1), that the switch lever has three different positions and that when it is in the middle position the switch is released so that it can be operated locally. The apparatus in question are probably intended for this purpose, but those which we use have the following arrangement.

The switch handles or levers are of the same type as those for switches operated from a distance *only* and which can be cut open when the lever is in the normal position or in the thrown-over position. In the case of wire transmission, a special lever is used which is interlocked for the local operation. When the switch is operated locally, the effect is the same on the switch handle or lever, as when the switch is cut open by a train.

As a general rule, a locking pulley must be used with these switches operated from a distance and locally, in order to prevent local operation when the main signal in standing at line clear, for with the existing types the switch lever is cuttable when the route lever is in the thrown-

(1) See also *Bulletin of the Railway Congress*, January, 1910, p. 334.

over position. The same is not the case for the switch handle; however, the locking pulley is considered necessary for switches taken from the facing side.

These apparatus are used by us rather extensively. At small stations, where a single central frame suffices, the switches which have to be operated for the combination of the different routes are arranged, so that they can be operated from the cabin, and those of the switches which have to be operated during train movements, are also arranged so that they can only be operated locally. Thanks to this organization, a single employee looks after the service of the signals and switches, when trains cross and pass each other. As regards shunting operations, they do not require the presence of a signalman in the cabin, as all the switches concerned can be operated locally.

Installations of this kind have been adopted since 1896 at about one hundred and ten stations and at present fifteen others are being equipped in this way; they have been recognized, from the economic point of view, to be the most advantageous for little stations where trains cross each other.

KLEMMING.

Stockholm, 1 July, 1910.

APPENDIX II.

[656 .257 & 656 .21 (01] —

Note on the M. D. M. system. Installation in cabin XI (Landy), Paris-Nord,

By Anon.

General observations.

The operation and controlling of the working of points and signals from a distance by means of power supply, such as compressed air, fluid under pressure or electricity, has now become a necessity in railway working.

It has become, in fact, necessary to increase the safety of the ordinary systems, to supplement the muscular energy of the operator, and to make the performance of the operations more rapid without increasing the number of signalmen.

To meet these requirements, cabins have been fitted with route levers. In such cabins all those details which represent the routes taken by the trains have been grouped in the first instance in the design and construction and are operated by a comparatively small number of interlocked levers.

Usually it is necessary to move a number of these levers in a certain definite order to clear a train. Such a system is necessarily complicated. Its execution requires lengthy study since it is necessary, in order to be prepared for all contingencies, to provide for numerous combinations in addition to those normally required.

In the tangle of electric leads and pipes only a specialist knows what to do. On the other hand, the signalmen do not realize exactly what function they perform and their attention is generally taken up by the levers instead of being directed to the track.

Finally, should a modification suddenly be found necessary which has not been provided for, it is difficult to deal with it because it is impossible to change entirely, in a few minutes, the grouping and interlocking which have been arranged.

It is therefore necessary to use makeshift und uncertain arrangements over a period of time which is always too long when safety has to be considered.

In the M. D. M. system, an endeavour has been made to eliminate all complication. With this object, while realizing the idea of the route lever or key which is found desirable by the traffic department,

the principle of individual levers is retained because this is the simplest, the clearest and the only system which lends itself to all combinations.

The characteristics of the M. D. M. system are as follows :

1° Each point or signal is represented individually in the cabin;

2° Operation at one movement and by means of a single key, of the point and signals of each route.

All the sets of points are operated simultaneously and the route is made in the shortest possible time.

The signalman is therefore free to devote his whole attention to watching the tracks;

3° Route keys grouped in a " combiner" occupying but small space arranged as a " Table of Pythagoras " which is easy to read, and no training is required to understand it;

4° Interlocking effected immediately on operating and permitting of all combinations being made without either preliminary study or arrangement;

5° Positive and permanent indication of the position of the points, keeping the signal always in agreement;

6° Permanence of the interlocking so long as the signal is not set to danger (signal indicator) or so long as the train is still within the zone operated from the cabin (transit).

Characteristic features of the M. D. M. system.

I. *Mechanical route combiner.* — The mechanical combiner is the appliance in the cabin which effects the characteristic methods of operating enumerated above.

It is the combiner which selects from the individual details, corresponding to the various points and signals, those combinations necessary for making the route and securing the interlocking.

The combiner is of rectangular shape. On the front it carries the references which the signalman may require to use and also the knobs or handles of the route keys.

There is one key for each route.

The same key is used for traffic in either direction.

In their neutral position the keys stand at 45°.

To make a route, it is only necessary to perform the operation of turning its key to the vertical or to the horizontal position according to the direction in which the route is to be used.

The keys are arranged in rows at right angles to each other, in which the horizontal rows refer to arrival tracks and the vertical rows to departure tracks or *vice versa*. The whole forms a " Table of Pythagoras ".

To make a route to connect an arrival track with a departure track, it is sufficient to look at the column and row referred to, and to turn the key which occupies their point of intersection.

To render the table more easy to read, the rows and columns are numbered. Each key is designated by the number of its row and of its column.

Thus the key 43, for example, is the key for that route which connects the arrival track represented by the row 4 with the departure track represented by the column 3.

Each row or column carries at its extremity an indicator signal showing the position of the signal giving access to the corresponding track.

When a route is made the key is turned towards the indicator of the signal to be pulled off.

The selection of the key and the direction in which it is to be moved are therefore capable of being grasped by anyone without special knowledge.

On the inside of the combiner, the points and signals are represented by metal planes parallel to the face of the board.

There is one plane for each set of points (point plane) and one plane for each arrival or departure track, either with or without a signal (track or signal plane).

The keys are perpendicular to the front face of the board and run through the combiner from front to back, passing consequently through all the planes.

When a key is required to control a plane it is fitted with a cam acting on that plane, otherwise it is without.

The cams are of two kinds, point cams and signal cams.

They present the following features:

1° When the key which carries them is in the neutral position the cams do not bear against the planes which are quite free;

2° When the key is turned they are displaced and then hold either to the right or to the left planes of which the corresponding sets of points are to be moved to the right or to the left;

3° Each plane so held, to the right for example, prevents the turning of any other key the rotation of which would tend to bring it back to the left.

The routes are therefore interlocked among themselves, because the sets of points common to both cannot be worked from two opposite sides at the same time.

All the interlocking arrangements between the routes which cannot be made simultaneously with safety, are thus effected naturally and without special gear (1).

This result applies generally. It is independent of the plan and of the arrangement of the routes, whether the points are for simple crossings, double slip points, or cross overs. It is obtained without scheming, since it depends on the one fact that any particular plane, that is to say, any one set of points, cannot occupy positions to the right and to the left at the same time.

The interlocking preventing traffic from running in opposite directions over the same route is even more simple: a single key cannot occupy both vertical and horizontal positions at the same time; hence it is not possible to make a route in two opposite directions at the same time.

It is this fact which explains the statement that *in the M. D. M. system no scheming for the interlocking is required.*

It follows that with the mechanical combiner of the M. D. M, system any change can be effected *immediately*.

By changing the number and position of the cams of a key, the plan of the route it controls can be modified as desired.

By the addition of a key a new route can be made with any of those existing, and this can be done without troubling about the interlocking involved by the operations, irrespective of their number and arrangement.

So far, in the description of the combiner, nothing has been said of the way in which the planes are connected with the points and signals to which they correspond. Any kind of power supply can be used for the transmission.

We shall not discuss here the arguments which may decide the selection of one kind of power supply rather than of another. We shall confine ourselves to stating that in the applications already made, or being installed, hydraulic power is used (glycerine being added to the water in winter) in the case of transmission of force to a

(1) Tracks which cross each other are treated similarly to points; this is, however, unnecessary where there is a loop track.

distance, and compressed air at low pressure is used as the motive power.

The water acts the part of a connecting rod between the combiner and the motors.

This transmission of power by fluids is economical, free from risk of short-circuit, and has the advantage that its efficiency can be checked directly by the natural senses.

The pressure used for the hydraulic portion of the system is about 8 kilograms per square centimetre (114 lb. per square inch). The air is compressed to from 5 to 10 kilograms per square centimetre (71 to 142 lb. per square inch) in a receiver. It is used at a reduced pressure, about 3 kilograms (43 lb. per square inch), for operating the points and signals. It is also used for the supply of water under pressure, by means of a simple and compact ram which acts as a hydraulic accumulator, permanently at full lift.

It will be seen that in the M. D. M. hydro-pneumatic cabins, the only power to be supplied is the compressed air. The Aster Company have constructed very small compressors for this purpose, of particularly simple and strong construction, requiring practically no maintenance and capable of being run direct by electric motors or paraffin oil engines.

In the event of failure of the compressors a locomotive fitted with a compressed air brake can be brought up to the cabin and used temporarily.

Finally, if no locomotive is available, the motors at the points can be worked by hand, independently of the power supply.

II. *Controllers.* — By this term are understood those appliances which show that the point blades are home against the stock rail and also show the position they occupy in relation to that of the planes which represent them in the cabin.

The control of a route is effected by sending hydraulic pressure through a pipe to the departure end of the route and passing this to each set of points of the route in the opposite direction to that which will be taken by the train, that is to say, it is supplied first to the end of the route which the train will leave, and last to the end at which it enters.

When the pressure reaches the entering end, it returns thence to the cabin and operates the signal. Thus it is the pressure in the control pipe which throws over the signal.

In the cabin, the outward flow and return of the pressure in the control pipes is effected as follows :

It has been shown above that each of the tracks entering and leaving is represented in the combiner by a plane. On turning the key corresponding to a route, the planes corresponding to its entering and leaving tracks are simultaneously moved. The displacement of the plane corresponding to the leaving track admits the pressure to the control pipes which are laid along the route which it follows as already explained.

The displacement of the plane corresponding to the entering track admits the pressure in the control pipe to the entering signal of the route, when it has completed its travel along the track.

Between the leaving track and the entering track the pressure in the control pipes travels as follows :

Each set of points is fitted with a *controller*, which is a sort of valve, open when the points are home *in the direction to which they have been set* by the combiner, and only for the period of operating, being closed in all other cases.

When the valve is open the pressure is admitted. When the valve is closed, on the other hand, it cannot pass and the

Fig. 8. — Signal controller carried on the post.

Fig. 9. — Auxiliary controller attached to rigid rodding.

signal at the entrance to the route remains at danger. The controllers represent the points and the intermediate pipes represent the tracks. The control is consequently an exact representation of the system of tracks.

It follows that the control pressure on being admitted to the controllers of a set of points is transmitted thence to the next and thence to the next, and so on, thus completing the route.

If a set of points does not occupy the desired position, it stops the transmission of the pressure and the signal is not pulled off. If at any time and from any cause whatever anything goes wrong, the pressure ceases to be transmitted and the signal returns to danger.

To sum up : in order that the entering signal of a route may occupy the line-clear position it is necessary that :

1° The key corresponding to this route should be turned in the proper direction;

2° That the points along this route should each be thrown over fully or held fast and that the point tongues should be home against the stock-rails.

The control is therefore positive and permanent.

There are some points worthy of notice in this method of controlling :

1° If the pressure in the control pipe finds a continuous passage enabling it to connect the leaving and entering ends of the route, then the tracks also give a continuous route ready for the train to enter;

2° From the fact that a set of points cannot simultaneously be set to the right and to the left, a natural form of interlocking is afforded on the tracks, obtained from the position occupied by the points, of a similar character to that given by the planes in the combiner, which correspond to the respective points and in fact it is a kind of duplication of this; this amounts to the same thing as stating that it is just as impossible to obtain simultaneously from one set of points (1) on the track the control of routes which would form an unsafe combination as it is impossible to transmit from the combiner in the cabin controls which in combination would be unsafe.

This property of the system, taken in conjunction with the individual character of the operating gears, enables the most complex routes for connecting entering and leaving tracks to be made at once, even without the route keys. This is a valuable advantage in cases of alteration to the tracks or of sudden change in the method of working.

The control is sometimes supplemented by an electrically-operated indicator board in the cabin, which shows the tracks and the position of the points. This apparatus is merely an indicator. It has no action on the position occupied by the points or signals.

III. *Signal controllers.* — It is important that the return of the route key to its normal position, and the consequent release of the interlocking arrangements, should not be possible before the signal controlled by that key has been actually set to danger. The signal controller effects this in the following manner :

Every signal when at line clear practically locks the track plane which set it to line clear.

The key, which was turned to cause the clearing of the route, is capable of being

(1) When two tracks cross without connecting points, a controller is arranged at the crossing which acts in the same manner as if the crossing were a set of points.

turned through an angle sufficiently large to ensure the return of the signal to danger. It cannot, however, complete its rotational movement until the track plane has been freed, that is to say until after the signal has completely and actually returned to danger.

The movement of returning a route key to its normal position when this controls its signal must necessarily be performed in two steps:

First step: partial rotation of the key, signal returns to danger;

Second step: completion of the rotation of the key, freeing of the interlocking arrangements.

IV. *Transit. Block system.* — The transit is a form of interlocking which prevents the route key from being returned to normal from the moment the train has entered the section operated from the cabin until the last pair of wheels has cleared the section.

To ensure this, the train itself locks the plane of the combiner corresponding to the leaving track so soon as it enters the route and it only releases it when it leaves the route.

The connection between the entering and leaving tracks is fixed by the combiner, by the position occupied by the key itself, that is to say at the intersection of the row which corresponds to the entering track with the column which corresponds to the leaving track.

To the transit is sometimes added the block system. In this case, the signal cabins adjoin the rows and columns of the combiner. The keys when turned couple them in pairs.

Usually this connection is all that is required, but in some cases the setting of a signal arm to line-clear causes a key connecting two cabins to be locked.

V. *Backing down.* — The routes over which backing down operations are effected are generally incomplete. They are however true routes, and, for this reason they are provided for in the general scheme of the M. D. M. system. Under these circumstances the solution of the problem presented by backing down, does not require any special consideration apart from those already set forth.

VI. *The M. D. M. auxiliary controller.* — In the first application made of points-controllers of the M. D. M. system in 1907 at the Cabin A at Landy, some of these were connected to the points by rigid rodding of considerable length.

The regularity with which they operated, under special conditions, led to the idea of using them "to ease the heavy pulls" in cabins fitted with Saxby apparatus.

The connection is made in the following manner:

The points-controller is placed at the base of the cabin and is connected rigidly to the rodding.

An M. D. M. transmitter is fitted adjacent to the Saxby lever, to which it is coupled by a strap-ended connecting rod.

Two fluid connecting rods are employed between the transmitter and the controller, the one for bringing to normal position and the other for throwing over.

The mode of operating is as follows:

When the lever in the cabin stands in its normal position, the points and the controller which are rigidly connected to it by the rodding, are normal also.

If the lever is moved from the normal position, the controller comes into action at once and assists the operations until the lever is thrown completely over and the points are also thrown over.

In the converse movement, the control-

ler acts in restoring the points and the lever to the normal position.

By varying the air pressure admitted to the M. D. M. auxiliary controller the force exerted by it can be increased or diminished.

The M. D. M. auxiliary controller can therefore, at will, only give assistance to the signalman, or on the other hand, can of itself perform the operation as rapidly as may be desired,

Should the pressure fail, the signalman can move the Saxby lever just as though no auxiliary controller were fitted.

REPORT

By Mr. von STIERLIN,

PRESIDENT OF THE MANAGING COMMITTEE OF THE GENERAL ADMINISTRATION OF THE WURTEMBURG STATE RAILWAY.

The object of this question, on which I have to report, is supply members of the International Congress with information on the subject of the different ticket systems at present used by the railway administrations of the different countries and thus to show what alterations and improvements have been made as compared with former times.

The discussion of this subject appears to me very advisable for the following reasons :

1° The continual increase in the passenger traffic on the one hand, and economic reasons on the other, make it necessary that the dispatch of passengers should be quick and simple, and that at the same time abuses should be prevented as much as possible. It is therefore to the advantage of every administration, to examine the ticket system of other large administrations, in order if possible to benefit by it;

2° The continued growth in the traffic in the different countries is always making new demands on the railway administrations, from the point of view of the fares charged for the conveyance of passengers. As a result, the necessity from time to time arises, of changing the fares or of introducing new tariffs, and this also involves corresponding changes in the existing patterns of tickets used, or the issue of new tickets.

In order to carry out my work, I have in accordance with the wording of the question (Passenger tickets : Different types of passenger tickets. Systems enabling

*

the number of blank tickets to be reduced. Simplified tickets for stopping places. Apparatus for printing tickets [and checking them] as and when required.) drawn up a list of questions and sent it to seventy-five of the more important railway administrations in the different countries. Fifty-seven of these administrations sent replies.

I think I can best describe the conditions existing by giving a summary of the answers received to the individual questions. In addition I have prepared, from the specimens sent to me, a typical collection of tickets of different patterns which I will exhibit at the Berne Session.

REPLIES TO THE VARIOUS QUESTIONS.

QUESTION 1. — *Of what shape are the tickets you issue, and of what material are they made?*

The information collected shows that tickets are everywhere made of card or of paper, of different colours and shapes. The ordinary shape of a card ticket is that of the so-called Edmonson ticket (about $57 \times 30{\cdot}5$ millimetres [$2\,{}^{1}/_{4} \times 1\,{}^{3}/_{16}$ inches]). Among paper tickets we may mention book tickets and books of tickets, *i. e.* tickets bound in the form of books with a stiff or a limp cover. The separate pages are either coupons for the different sections of the journey or tickets for a given journey (tickets for a given number of journeys over one and the same section). In the case of season tickets, linen paper is frequently used because it is more durable.

Besides the rectangular shape which is the most usual, we have to mention tickets of octagonal shape, used in France, South Africa and Australia, and tickets of oval shape, used in France and in Australia.

Besides card and paper, the following materials are also used for tickets :

Leather, for season tickets in England, France, Austria-Hungary and Australia.

Metal, for season tickets in Australia. These metal tickets (annual tickets, partly of gold) are of round or of oval shape (about 25 to 35 millimetres [1 to $1\,{}^{7}/_{16}$ inches]); and are made to hang on. The section for which the ticket is available is indicated by letters or numbers.

One peculiarity of American tickets is that some of them are printed on very long strips of paper; I have received specimens up to 139 centimetres (4 ft. 6 ${}^{11}/_{16}$ in.) long by 7 centimetres ($2\,{}^{3}/_{4}$ inches) wide (apart from mileage coupon books).

Question 2. — *Are tickets of different shapes issued? If so :*

a) What were the reasons for the individual shapes?
b) What shape of ticket is most used?

---

a) Germany : In the case of journeys at the ordinary tariff rates, particularly in the home traffic of the individual administrations, Edmonson tickets are used, which are made of a standard shape for technical, traffic and economical reasons, as well as for the convenience of passengers. All other shapes are on account of special clauses in the tariffs and of provisions in connection with the accounts and controls, or on account of agreements with other administrations; for instance in the case of season tickets, it was necessary to adopt a larger size as more had to be printed on them, and in order to distinguish them more readily from the other tickets. The tickets which may be used at the passenger's option for varied routes on different railways are issued either as books of tickets or as Edmonson tickets with a piece to be cut off for purposes of control.

England : The different shapes are intended to define the nature of the tickets; each kind of ticket is to have a special character.

France : The shape of the tickets is dependent on agreements made between the French railways with a view to the through traffic.

Italy : The conditions under which the tickets are used, the statements which have to be found on the tickets, such as the route to be followed, the record of where the journey was interrupted, etc., have led to the use of tickets of different shapes.

Holland, Russia : The different shapes of the tickets are dependent on the different tariff regulations.

Austria-Hungary : The reasons for the different shapes were the convenience of use, considerations as regards control (for instance, when several administrations are concerned), local requirements, as well as the amount of printing which had to be on the tickets (for instance, in the case of season tickets).

Switzerland : The Edmonson tickets are the simplest and the most rational; the reasons for the other shapes were : facilitating the control and the settlement of the accounts.

North America : The shapes are suited to the conditions under which the tickets are issued. Where there is much traffic, card tickets are used, as these are easier to manufacture and to issue than the simplex tickets.

The other administrations questioned give similar answers.

b) According to the answers received, the Edmonson card ticket is everywhere the shape of ticket most used.

Besides the Edmonson tickets, the following were mentioned :

Dutch State Railway : kilometre books.
Hungary : paper tickets.

QUESTION 3. — *If special tickets (express tickets, return tickets, circular tickets, season tickets, etc.) are issued for certain trains or for special purposes, please send us a list of the different kinds issued.*

Germany : Besides the tickets which are available for all trains, and which have a longitudinal red stripe on them, the following are issued : tickets for express and passenger trains, double tickets (the one half is collected when the single journey is completed, the other serves for the return journey), return tickets to the seaside places on the coasts of the North Sea and the Baltic; mixed tickets (tickets with imprint available at different stations, to which the fare is either the same or different); excess tickets for express trains; soldiers' tickets; tickets for special trains; Sunday tickets; continuation tickets; children's tickets; sleeping-berth tickets; excess tickets for transfer to a higher class; workmen's weekly tickets for single journeys and also for return journeys (the latter are available for 12 journeys; at each journey a hole is punched through the ticket at the corresponding numbered spot. Besides these, there are also workmen's weekly tickets in Wurtemburg and Baden, which in order to accelerate the control are not punched at the ticket barrier. They are available for one week; the weeks in the year are numbered successively, and the corresponding number is stamped in large and clear figures on the ticket; (in weeks where there are one or more holidays tickets are issued available for five or four days); workmen's return tickets; workmen's monthly tickets; circular tickets; books of tickets made up in various combinations; tickets of the tourist agencies; season tickets, for periods of from 1 to 12 months; monthly tickets; monthly supplementary tickets; pupils' tickets; tickets to watering places; summer tickets; soldiers' passes; passes for special trains, and special carriages; passes for school excursions; tickets for men accompanying live-stock carriages; dog tickets.

Belgium : Return tickets available to one of more stations (tickets for one given station are issued to stations with much traffic or if the receipts from these tickets have to be divided with private railways; tickets available to several stations are used, in order to simplify the work of the ticket clerks, and to reduce the number of the blank tickets which have to be written out; three destinations can be printed on one ticket); tickets for parties, for emigrants, for excursions and for tourists; circular tickets; season tickets for 5 days and 15 days, and for 3, 6, 9 and 12 months,

available on all the Belgian lines; season tickets for 3, 6 and 12 months available on a given line only; pupils' tickets for 3 and 6 months, and for the academical year; workmen's weekly tickets for the single journey and for the return journey (these tickets are of two kinds, 7-day tickets, available from Sunday to Saturday inclusive, and 6-day tickets, available from Monday to Saturday inclusive).

Bulgaria : Return tickets; circular tickets; books of tickets made up in various combinations; season tickets.

Denmark : Ferry tickets; excess tickets; circular tickets; monthly tickets available between certain stations or on all lines; fortnightly tickets available over the whole of the State Railway; emigrants' tickets; books of tickets made up in various combinations; station tickets, available for one uninterrupted journey on a passenger train or on a mixed train to the station, or to one of the stations, indicated on them. In addition, between stations 30 kilometres (18·5 miles) apart, as well as on other sections with much traffic, tickets are issued, which are available either for a single uninterrupted journey on the train for which they are taken, or which may be used, in the opposite direction, for trains which start before midnight of the day on which they are issued (these tickets are shortly to be replaced by return tickets without reduction of rate).

England : Return tickets; children's tickets; excursion tickets; soldier's tickets; sporting tickets; seaside tickets; tickets for commercial travellers, emigrants, tourists; Sunday tickets; market-day tickets; workmen's tickets and workmen's weekly tickets; tickets available from Saturday to Monday or from Saturday to Tuesday; circular-tour tickets; tickets for special trains; season tickets available on given sections for periods of from 1 to 12 months.

France : Mixed tickets; soldiers' tickets; return tickets; tickets for visiting watering places; tickets for pilgrim trains and excursions trains; emigrants' tickets; tourist tickets; racing tickets; family return tickets; workmen's tickets and workmen's weekly tickets; circular-tour tickets, books of tickets made up in various combinations; season tickets for 1, 3 and 12 months; books of tickets for 20 journeys on a given section; dog tickets.

Italy : Return tickets; express tickets; supplementary tickets; circular-tour tickets (in order to avoid the necessity of having different kinds of these tickets, some of them have a separate section for each class, first and third, in different colours; and a separate section for each of three different tours; by removing the class and tour sections not required in a given case, the ticket is prepared for the class and tour desired by the passenger); book of tickets made up in various combinations; season tickets of several kinds, ordinary, pupils' and special (the latter are available on given sections for 15 or 30 days, 3 months or a year).

Holland : Return tickets; Sunday tickets; soldiers' tickets; tickets for D-trains

and for excursion trains; market tickets; tickets for parties; emigrants' tickets; cyclists' tickets; workmen's weekly tickets; holiday tickets for July, August and September; workmen's holiday tickets; circular-tour tickets; books of tickets made up in various combinations; pupil's tickets; tickets for 10 journeys on a given section; kilometre books (each journey is entered on the different pages; the departure and the arrival stations are mentioned, and also the distance; the distances are added up from time to time); season tickets.

Norway : Tickets for journeys on the local trains; single tickets and return tickets (these tickets are used where the rate for several different sections is the same); mixed tickets for single as well as for return journeys (several stations with different rates are designated on the tickets; the tickets are cut through at the station of destination; the part with that station on is issued to the passenger, the other is kept by the ticket clerk); children's tickets; excess tickets; family tickets; monthly tickets; workmen's tickets in books of 12 tickets (weekly tickets) and in books of 50 tickets (monthly tickets); circular-tour tickets; tourist tickets; books of tickets made up in various combinations; sleeping-berth tickets; dog tickets.

Austria-Hungary : Return tickets; tickets for special trains; half-price tickets; express tickets; supplementary tickets for express trains; combined tickets (available by express train on part of the journey and by ordinary train on the other part); soldiers' tickets; Sunday tickets; tourist tickets; tickets to watering places; excess-fare tickets; servants' tickets; workmen's tickets and weekly tickets; tickets for reserved seats; sleeping-berth tickets; books of tickets made up in various combinations, season tickets for 6 and 12 months on all lines (in small cases with the photograph of the passenger stuck in); pupils' tickets; tickets for a given section (when these tickets are issued, they are cut through below the number of months, for which they are available; the cut-off upper part is stuck on the back of the photograph of the holder); subscription tickets for travelling if half the fare is paid (in a small case with photograph); season tickets available for 15 and 30 days on certain given sections; passes for soldiers' and for civilians; passes for men accompanying corpses, animals and other consignments.

Rumania : Return tickets; tickets for visiting watering places and health resorts; children's tickets; soldiers' tickets; tickets for excursion trains, for the Orient express, the Ostend express and the Berlin express; circular-tour tickets; books of tickets made up in various combinations; season tickets for the whole railway system or for part of it, and available for 1, 3, 6 or 12 months (in the form of a book, with the photograph of the holder); excess tickets on the trains.

Russia : Suburban tickets; express tickets; return tickets; zone tickets; mixed tickets for different stations with different fares; excess-fare tickets; tickets for pilgrim trains; tickets for reserved seats; season tickets.

Sweden : Double tickets; express tickets; tickets at reduced fares; soldiers' tickets; excess-fare tickets; sleeping-berth tickets; stopping tickets; special-train tickets; monthly tickets; tickets for 20 journeys between given stations; passes for military transports; books of tickets made up in various combinations; tickets for the tourist agencies.

Switzerland : Return tickets; tickets at half price; tickets for change of class; supplementary tickets for travelling by a longer route; workmen's tickets; Sunday tickets; tickets for pilgrim trains; circular tour tickets; singles and returns to the Bernese Oberland; control checks for party tickets, school tickets and kilometre books; tickets for the agencies in London and Paris; books of tickets made up in various combinations; tickets for tourist agents; tickets for parties and schools; supplementary tickets, station and train staff; excess tickets of train staff; tickets for extra charge for express trains on foreign sections (in Switzerland itself there is no extra charge for express trains); emigrants' tickets; tickets for English parties; workmen's monthly tickets; season tickets, for 24 single journeys and for 12, 25, 50 or 100 double journeys on given sections; season tickets available on all trains given in the timetable; pupils' tickets; season tickets fort wo members of the same firm; general season tickets (with photograph of holder stuck on) for 15, 30 and 45 days, 3, 6 and 12 months; general season tickets for two persons for 12 months; kilometre books (these parate pages are divided into 1 kilometre (0·62 mile) sections and the photograph of the holder is stuck on).

Spain : Return tickets; family tickets; mixed tickets; children's tickets; soldiers' tickets; excess-fare tickets; supplementary tickets; circular-tour tickets; kilometre books; season tickets.

United States of America : Return tickets; special-train tickets; excursion tickets; tickets for trains consisting of Pullman cars only; circular-tour tickets; tourist tickets; season tickets available for one ore more months; tickets for 10, 25, 50, 55, 60 or 100 journeys between given stations; mileage books for 500 miles (the separate pages are divided into 20 sections of a mile each); mileage books for 500, 1,000 and 2,000 miles (these are printed on long strips of paper divided into sections of 1 mile or of 5 miles; a stiff cover is provided). Then we also have to mention the so-called simplex, multiplex and lomax tickets; their object is to avoid having too many printed tickets. They are made of paper; a number of destination stations are printed on them. The destination of the passenger is marked in the case of the simplex and lomax tickets by a cut which corresponds with the part remaining at the station; in the case of multiplex it is marked by putting in perforations above and below the name of the destination station.

Argentine Republic : Return tickets; excursion tickets; workmen's tickets; week-end tickets, (issued on Saturdays, Sundays, feast days or the day before; the return journey is made on Monday, or on Tuesday if the Monday was a holiday. The

tickets issued on feast days and on the day before are available on the next working day after the feast day); excursion tickets; holiday tickets on special occasions such as the Carnival, Easter, Christmas; season tickets for 1, 3, 6 and 12 months; zone tickets for railway employees.

Mexico : Return tickets; mixed tickets; circular-tour tickets.

India : Return tickets; tickets for the servants of first and second class passengers; workmen's tickets; tickets for markets and fairs; pilgrim tickets; troop tickets; tourist tickets; tickets for standing room; tickets for limited trains; circulartour tickets; monthly tickets.

Egypt : Return tickets; mixed tickets; books of tickets; season tickets.

South Africa : Return tickets; children's tickets; family excursion tickets; season tickets; books of tickets for 20 journeys over given sections; mileage books (the pages are divided into small sections of 1 mile each).

Australia : Simplex tickets with the names of several destination stations printed on (they are used on sections, where there are many stations without booking offices, and are issued on the train; they save many blank tickets and excess-fare tickets); tickets for excursion trains; excess tickets for going on beyond the destination station of the ticket or for changing from one class to another; circular-tour tickets; excursion tickets; pupils' tickets; season tickets for 1, 3 and 12 months either for all the lines, or for given sections only.

QUESTION 4. — *Are your tickets kept ready printed at the booking offices, or are also printed forms provided which the ticket clerk has to fill up in writing in each separate case (blank tickets)?*

In Denmark all the tickets are supplied ready printed to the stations, the monthly tickets are issued chiefly by the head office.

All the other administrations have at their stations not only ready-printed tickets, but also blank tickets (tickets on which certain forms are printed, and on which the booking clerk has to fill in the destination station, the route and the fare). The French Northern Railway is, as an experiment, trying at one of its booking offices a machine for issuing blank tickets. This was constructed by the firm « l'Appareil Contrôleur » in Paris and resembles the machine used for printing Edmonson tickets (compare question 14).

QUESTION 8. — *If blank tickets are used, please inform us :*

a) In what cases are they issued ?

b) How is their issue controlled and checked ?

---

a) In *Denmark* no blank tickets are at present issued. In all other countries they are issued .

1° In the case of connections with but little traffic, for which there are no printed tickets;

2° Instead of printed tickets, if the supply of these happens to have become exhausted.

In addition, blank tickets are used by some administrations for the purpose of excess-fare tickets if a passenger travels beyond his destination station or changes into a superior class.

The rules as to how much traffic there must be before ready-printed tickets for a given journey are supplied vary considerably in the different countries. The following information is collected from the answers of several administrations. Ready-printed tickets are supplied in the following countries if the minimum issued per year is not less than :

Germany	12 to 25	Spain	600
Belgium	25 to 36	U. S. A.	180
England	4 to 50	Argentine Republic	25 to 36
France	12 to 144	India	12 to 50
Holland	120	Egypt	24
Rumania	60	Australia	25 to 36
Russia	20		

b) In most countries, the tickets are issued from duplicate books, the original being kept by the station while the passenger receives the carbon as ticket, or else the blank ticket has a section which has to be filled in like the ticket and is retained by the station for the control after the ticket has been separated from it. These stubs are sent together with the accounts to the controlling office, and checked there. The blank tickets of some administrations (for instance in Austria and in the United States) have a third section which is collected by the conductor when the journey is begun and which is also sent to the controlling office. In addition, the blank tickets are collected by the conductors at the end of the journey and are sent to the controlling office, which compares them with the accounts of the stations. As check that no ticket is sold out of the proper order, there are the consecutive checking numbers printed on them like on the other tickets. In cases when the blank tickets have no special sections for purposes of control (ordinary Edmonson tickets as in Belgium, Holland, India, Egypt, Australia; partly also in England,

France and Norway), the control is effected merely by the checking numbers and by a comparison of the tickets with the accounts of the stations.

The *Italian* blank tickets consist of a piece of card or of paper. On the one side there are the tens, on the other side the units of the lire, placed one under the other (fractions of lire are not given). When the ticket is used, the card is cut at the points corresponding to the price of the ticket in such a way, that the fare is shown. The passenger receives the one part as his ticket, the other part is retained by the issuing stations as check. If part were subsequently cut off from both parts of the ticket, the fare shown would be altered and would be increased on the part retained by the station and reduced on the other part.

In *Rumania*, the blank tickets consist of two Edmonson tickets joined together; on them are printed the name of the issuing station and also the price of the ticket in whole francs; the booking clerk has only to enter the class, the destination station and the centimes. There are 60 different blank tickets, from 1 to 60 francs (from 9·6*d.* to £2.8*s.*); the latter amount is the highest which can occur. The one ticket is detached by the booking clerk and serves as check.

In India there are in some cases different blank tickets for distances of up to 100 miles, from 101 to 250 miles, from 251 to 500 miles, and over 500 miles.

Question 6. — *Are you taking any steps, other than supplying printed tickets, for reducing the number of blank tickets?*

Question 7. — *If so, please give us particulars of these steps.*

Germany : Several passengers travelling together to one station can be booked by one single blank ticket (also adults and children together), namely four first-class, six second-class, and eight third and fourth-class. In the case of blank tickets for soldiers, there is no limit to the number which can be booked by one ticket. In the case of school excursions, one joint blank ticket is used.

France : Parties (musicians, members of scientific excursions, etc.) receive one joint ticket.

Austria-Hungary : Parties belonging together and consisting of more than 6 members receive one joint ticket.

The provision that several persons can be booked by one single blank ticket also exists, to judge by the sample tickets sent, in England, France, the United States, the Argentine Republic and South Africa.

Among such devices we must also include the mixed or group tickets mentioned under question 3. On these tickets the names of several destination stations, to which the fare may be the same or may be different, are printed; in this way the

stocking of ready-printed tickets for each separate destination station or the issue of blank tickets is avoided. Such tickets exist in Germany, Belgium, Denmark, Norway, Russia, Spain, the United States, Mexico, Egypt and Australia.

Question 8. — *Are special tickets necessary for admission to the station if no travelling tickets are taken?*

In the following countries special tickets are always necessary for admission to the station if no travelling tickets are taken :

Germany, Belgium, Bulgaria, Italy, Austria-Hungary, Spain, Egypt.

In the following countries, such special admission tickets are not necessary at all stations, but only at certain definite, generally larger, stations :

Denmark, England, France, Holland, Norway, Rumania, Sweden, India and Australia.

In the United States, there are only veryfew instances of the issue of special tickets for admission to the stations.

Such special tickets for admission to the stations are not issued in the following countries :

Switzerland, Argentine Republic, Mexico; and at present also Russia where however such tickets are shortly going to be issued.

In South Africa, such special tickets are only issued to hotel servants.

Question 9. — *If so, please send us some specimens and inform us :*

a) Whether the tickets are only available for one admission to the station?

b) Or whether season tickets are also issued and under what conditions?

c) What is the charge for a ticket?

d) Are such tickets issued free and if so in what cases?

Germany : a) Yes, and on the day of issue only. In some cases the regulation exists that tickets issued between 11 and 12 o'clock at night are still available next day.

b) Season tickets are not issued.

c) 10 pfennigs (1·2*d.*).

d) Free tickets for admission to the platforms are issued to persons who have business relations with the railway administration; to persons who must have access to the trains for delivering or fetching goods (particularly milk); in the case of some managements, to members of the Press, to persons who are employees of

the workmen's or women's protection societies, or who look after destitute emigrants, etc.

The following are admitted free of charge, without special tickets, to the platforms :

1° The employees of the railway administration, on duty.

2° The officials of the office of the public prosecutor, the courts of law, forestry and police; the post-office, telegraph, customs and revenue officials, if this is necessary for carrying out their duties on the railway; they must either be in uniform or produce an order from their superiors.

e) Persons who have business with any of the post offices or railway offices within the barrier.

d) The contractors at work within the barrier and their men.

Belgium : a) Yes, the tickets are only available for two hours.

b) No.

c) 10 centimes (0·96*d.*).

d) No. Certain officials are however allowed admission free of charge; some of them receive special passes.

Bulgaria : a) Yes.

b) No.

c) 10 centimes (0·96*d.*).

d) Admission is only free to the railway employees on duty.

Denmark : a) to *c*) There are tickets for one single admission (price 10 öre [1·34*d.*]), and season tickets for 3 months (price 2 kroner [2*s.* 3*d.*]; a deposit of 50 öre [6·72*d.*] has also to be made).

d) Yes, to certain local, civil and military officials; to persons who are authorized to trade, etc., when the trains arrive and leave; to servants of those hotels which send carriages every day to the station.

England : a) Yes.

b) No.

c) and *d*) In some cases free, in others 1*d.*

France : a) Yes, the tickets are only available for two hours.

b) No.

c) 10 centimes (0·96*d.*).

d) No, but the station officials are authorized to admit certain persons without tickets.

Italy : a) to *c*) There are tickets for one single and tickets for several admissions.

AVAILABILITY OF THESE TICKETS.	1st class stations, price.	2nd class stations, price.
Single admission	20 centimes (1·22*d.*).	10 centimes (0·96*d.*).
20 times, available for 2 months . .	3 lire (2*s.* 2 1/2 *d.*).	1·5 lire (1*s.* 2 1/2 *d.*).
40 — — — 6 — . .	5 — (4*s.*).	2·5 — (2*s.*).
80 — — — 12 — . .	8 — (6*s.* 5*d.*).	4 — (3*s.* 2 1/2 *d.*).

d) No.

Holland : a) to *c*) Tickets for one single admission (price, 5 and 10 cents [1 and 2 pence]), available for one hour only, and season tickets :

1° For 6 months, price 5 florins (8*s.* 4*d.*) Dutch Railway Company);
2° 12 — — 10 — (16*s.* 8*d.*) — — —
3° 12 — — 5 — (8*s.* 4*d.*) Dutch State Railway).

d) Admission free, if one desires to see the station master. Certain hotel servants and employees of tourist agencies receive free passes.

Austria-Hungary : a) to *c*) There are tickets for one single admission (price 20 heller [2 *d.*]) and season tickets for periods of one month and one year. Price of the tickets for one month, 3 to 4 kronen (2*s.* 5*d.* to 3*s.* 2 1/2 *d.*); for one year, 20 to 36 kronen (16*s.* 8*d.* to £1.10*s.*).

d) Tourists agencies and officials receive free passes.

Norway : a) to *c*) There are tickets for one single admission and also season tickets. The price varies at different stations :

Single admission . .	5 to 10 öre (0·67 to 1·34*d.*).
1 month	1·25 to 6·00 kronen (1*s.* 5*d.* to 6*s.* 9*d.*).
3 months	3·75 to 12·50 — (4*s.* 2 1/2 *d.* to 14*s.*).
6 —	6·00 to 25·00 — (6*s.* 9*d.* to £1.8*s.*).
12 —	10·00 to 50·00 — (11*s.* 2 1/2 *d.* to £1.16*s.*).

d) Representatives of the national committee for fighting the white slave trade are admitted free on proof of identity. The police has free admission to all the places to which the public is admitted. Porters and messengers awaiting the arrival of trains also have free admission.

Rumania : a) Yes.
b) No.
c) 20 bani (1·92*d.*).
d) No.

Russia : a) Yes.
b) No.
c) 10 copecks (2·88*d.*).
d) No.

Sweden : a) Yes.
b) No.
c) 10 öre (1·34*d.*).
d) No.

Spain : a) to *c*) Tickets for one single admission. (Price : 0·10, 0·25, 0·50 peseta [0·96*d.*, 2·4*d.*, 4·8*d.*]); tickets for 30 admissions (price : 7·50 pesetas [6*s.*]); season tickets for one year (price : 25 pesetas [£1]);

United States of America : a) Yes.
b) No.
c) 1*d.*

India : a) to *c*) Tickets for one single admission (price : $^1/_2$ anna [$^1/_2$ *d.*]) and season tickets for 3 months (price : 5 rupees [6*s.* 9*d.*]).
d) Reception committees of religious societies, etc., in some cases receive free passes.

Egypt : a) to *c*) Tickets for one single admission (price : 0·5 piastre [1·25*d.*]) and season tickets for 1 year (price : 50 piastres [10*s.* 5*d.*]).
d) Only to high officials.

South Africa : a) No.
b) and *c*) Monthly and quarterly season tickets. The price varies; as a rule it is 10*s.* or £1.

Australia : a) to *c*) Tickets for one single admission (price : 2*d.* to 3*d.*) and season tickets for hotel servants, 3 months, 7*s.* 6*d.*, 6 months, 12*s.* 6*d.*; 1 year : £1 at larger stations and 10*s.* at smaller stations.
d) No.

The platform tickets for one single admission are with hardly an exception card tickets of the Edmonson pattern. In the case of some railways the numbers 1 to 12 are printed on for the hours (a. m. and p. m.) in order to be able to check, by a hole punched, when the holder came on to the platform. Moreover, there are platform tickets which like the double and the return tickets consist of two parts, one of which is collected on admission to the platform and the other on leaving it.

In France there are, besides Edmonson tickets, also platform tickets printed on paper, 100 being bound together into a book.

The platform season tickets are made of card of larger size; the Italian tickets for a number of admissions are books with a stiff cover and contain a corresponding number of small coupons one of which is collected at each admission.

Question 10. — *Do you print the tickets yourself at your own printing establishment, or do you obtain them from some printing firm?*

In the following countries the railway administrations own printing machines, on which card tickets of the Edmonson pattern can be printed, while the other tickets, particularly the paper tickets, are obtained from some printing firm :

Denmark, England, France, Norway, Austria, Rumania, Sweden, Switzerland, Spain, Argentine Republic, India, Egypt, South Africa.

Germany : Generally speaking only the Edmonson tickets are printed at own printing establishements. Some administrations however also possess machines for printing card tickets of larger size. The other tickets are supplied by printing firms.

Belgium and Hungary : All tickets are printed at own printing establishments.

Bulgaria : The tickets are printed at the State printing establishment.

Italy : The tickets are printed at own printing establishment, except those intended for international traffic and requiring an imprint, which cannot readily be printed by fixed type. The paper tickets are exclusively supplied by printing firms.

Holland : The Edmonson tickets and some of the larger card tickets are printed at own establishment; the others are supplied by printing firms.

Russia : The card tickets are printed at the State printing establishment ; some of the paper tickets are supplied, in accordance with the regulations of the general assembly of the Russian railways, by printing firms.

United States and Mexico : The tickets are obtained from printing firms.

Australia ; The Edmonson tickets are printed partly in own printing establishment and partly in the State printing establishment, while the other tickets are supplied by printing firms.

The machines for manufacturing the Edmonson tickets are mostly supplied by the following firms : Gandenbergersche Maschinenfabrik G. Göbel in Darmstadt, E. Ravasse in Paris, and Waterlow & Sons in London.

Question 11. — *If you have any own ticket printing machines, which can print tickets other than the Edmonson tickets, please send description and illustration of these machines and state what tickets can be printed with them.*

Germany : Some administrations possess so-called two-size machines supplied by

the firm Göbel of Darmstadt, which can be used for card tickets measuring 70 × 46 millimetres (2 3/4 inches × 1 13/16 inches) as well as for Edmonson tickets. The machines are constructed like those used for the Edmonson tickets; when used for tickets of larger size special sliding carriages and funnels are put in instead of the ordinary ones. The Baden State Railway possesses a machine, also supplied by the firm Göbel of Darmstadt, which can produce card tickets of any size up to 135 × 65 millimetres (5 5/16 × 2 9/16 inches).

Belgium : There are machines for printing card tickets measuring 80 × 30 millimetres (3 5/32 × 1 3/16 inches), and so-called *talons valeurs* can be printed. These machines are constructed like those used for printing Edmonson tickets. The machines are supplied by the firm Göbel of Darmstadt.

Holland : With some machines it is possible to print, not only Edmonson tickets, but also tickets measuring 95 × 30·5 millimetres (3 3/4 × 1 7/32 inches). These machines are constructed like those for the Edmonson tickets. The length of the channel through which the tickets pass is such that it can hold either 5 small or 3 large tickets at a time. The larger size is used chiefly for holiday tickets.

Hungary : Besides the Göbel double printing machines with dry stamps used for printing Edmonson tickets, we also possess a Göbel five-colour rotary machine equipped with guilloche roller for tinted impressions, ten sets of six-figure numbering devices, perforating apparatus and cut-off mechanism; this is used for printing mixed tickets for journeys to neighbouring countries.

Question 12. — *Do you use ticket-counting machines, and if so, how are they constructed?*

Ticket-counting machines are not used in Bulgaria, Denmark, Italy, Russia, Sweden, United States and Mexico.

Germany. — *Prussia :* A four-figure counter fixed at the side of the machine forms a reliable control for the correctness of the consecutive numbering. In order to facilitate the control, the machine is fitted with a bell which rings as soon as 100 tickets have run through the machine. The top ticket must bear the same number as that shown by the counter. — *Alsace-Lorraine :* The machines are driven by electric motors. A crank mechanism moves the ticket carriage to and fro. The number of forward movements is recorded by a counter. After every 100 cards a bell is rung.

Saxony : The ticket-counting machines are fitted with a controlling wheel and

a bell mechanism; the latter sounds when 50 and 100 tickets have been counted; at the same time the dry stamp of the administration is pressed in. The counting machines are only used in the case of the tickets printed by means of hand machines. The tickets produced by the electrically-operated printing machines have at the same time the dry stamp of the administration pressed in; but these tickets are not counted over again by means of special ticket-counting machines. The tickets are made up in packets of 100 each; a machine marks on the side of this packet a black diagonal line, from the top left to the bottom right; this at once makes it evident if any tickets have been removed.

Belgium, Norway, Rumania and Switzerland : The counting machines are supplied by the firm Göbel of Darmstadt.

England : Ticket-counting machines are only used by some of the managements. The machines have two perpendicular tubes, one above the other, which are connected by a horizontal slide; there are two wheels with the numbers from 0000 to 9999 engraved; they register how many tickets have passed from the upper to the lower tube (London & North Western Railway).

France. — *State Railway :* The counting machine is driven by an electric motor; it has a six-figure counter which counts two tickets at each revolution; up to 450 tickets can be counted per minute. — *Paris-Lyons-Mediterranean Railway* and *Eastern Railway :* We have counting machines on the Ravasse system. The cards pass through the machine, one after another, so that the printed number on the ticket must agree exactly with the number shown by the counter. Although the machine works very rapidly, counting 4 cards each revolution, yet every discrepancy between the number of the ticket and the counter is at once noticeable, if the counter has been set to the same number as that of the first ticket. The machines are constructed so as to be operated by hand or by motor. When operated by hand, 10,000 tickets can be counted per hour; when operated by motor this number can easily be doubled (this information is taken from a circular issued by the firm E. Ravasse of Paris). — *French Northern Railway :* Counting machines with a drum which counts 4 tickets at each revolution and with a rotary counter are used. — *Orleans Railway :* The chief parts of the counting machine are two holders which are separated by a wheel mechanism with a pawl; the tickets to be counted are placed in the upper holder and drop into the lower holder, acting on the pawl which operates the counter. — *French Southern Railway :* We use counting machines on the Lecocq system. A description of these machines is given in the *Revue générale des chemins de fer* for December 1880.

Holland : The counting apparatus is combined with the ticket printing machine. The tickets are counted before they leave the holder. The construction is generally speaking the same as that of other printing machines.

*

Austria-Hungary. — *Austrian State Railway :* The counting machines are so arranged that the printed tickets receive there the deep imprint and are counted by special control counters, which are operated by the tickets as they leave the machine. — *Austrian Southern Railway :* The counting machines consist of an entrance channel, an open passage for the tickets and an exit channel. At the side of the passage a four-figure counter is fixed, which controls the correctness of the succession of the numbers. — *Hungary :* There are five counting machines, four on the Göbel system (Darmstadt) and one on the Kärig system. The counting machines stop automatically each time 50 tickets have been counted.

Spain : Counting machines are available, but they are not used, as they are not practical. The machines only show how many printed tickets there are, but do not indicate any errors in the numbering or the printing. The officials in charge of the printing count the tickets by hand, and go through them a second time before packing them up.

Argentine Republic, India and Australia : Counting machines manufactured by the firm Waterlow & Sons of London are used.

Egypt : Counting machines are used for the Edmonson tickets.

South Africa : Waterlow's improved counting machine is used. The tickets are placed in a tube; a handle is turned by hand and the number is shown on a counter. The tickets when leaving the tube pass over a plate, where the numbers on the ticket can be read and checked.

Question **13.** — *Have you any machines by means of which the ticket clerk can print tickets in individual cases, the tickets being checked at the same time?*

Question **14.** — *If so, please send a description of such machines and inform us what results have been obtained with them. Please send a figure of such a machine?*

Such machines are only in use in Germany, Belgium, France and Holland, and in some cases as an experiment only.

The administration of the Atchison, Topeka and Santa Fe Railway writes :

" Numerous efforts have been made to produce a machine that would print railroad tickets as sold. However, I do not think that any machine has yet been produced that is satisfactory. All machines of this character have as their prime feature the adjustment of a die, the turning of a crank, etc., all of which takes time and delays passenger; in addition to this, the fact that these machines are, as a rule, extremely complicated, and the possibility of their getting out of

order at a critical time, prompts the belief that a satisfactory machine of this character will never be produced."

Germany : On some of the stations of the Prussian-Hessian State Railway there is a machine built by the firm Regina of Kalk near Cologne; the Cologne Directorate reports on 23 December 1907 as follows on the subject :

" The machine supplied by the firm Regina of Kalk for trial has been in use at the chief station here since 1 September 1907. It prints 1,280 different tickets to 324 stations, third class, tickets available for all trains, for express and passenger trains, soldiers' tickets and dog tickets. It occupies comparatively little space, as it is 1·10 metres (3 ft. 7 $^5/_{16}$ in.) long, 0·60 metre (1 ft. 11 $^5/_8$ in.) wide and 1·20 metres (3 ft. 11 $^1/_4$ in.) high. The design is simple, the construction is solid and strong.

" The machine consists of two main parts: *a*) the underframe; *b* the printing machine proper or the printing press.

" The underframe contains the 1,280 printing plates corresponding to the different tickets, in several vertical holders placed next to each other. The stations to which tickets can be printed are given on an alphabetical list fixed to the underframe. The press is then set to the station and class desired by moving forwards, backwards and sideways, an operation easily carried out. The press has a lever mechanism; by turning the cranked handle this mechanism raises the plate required from the holders to the printing table, and after the printing replaces it again in its original position; the printing table is operated by a can which presses the tickets card against the plate. The cards used for the purpose are cut up just like those used in our other ticket printing establishment. Before the printing operation the card must be placed by hand in the opening of the press. No special skill is required for any of these operations. They are easy and do not require any strength. The clerks consequently acquire in a short time so much skill, that the operations are carried out quickly and with certainty.

" Whenever a ticket is printed, then two controlling strips are applied simultaneously and the following information is uniformly printed on: 1° the number of the ticket; 2° the destination station; 3° the kind of train; 4° the class; 5° the fare; 6° the assessment of the duty.

" The clerk has access to the one controlling strip for making up his accounts; the other is under lock and serves as check.

" The machine presents accordingly the following advantages:

" 1° The control can be depended on. The receipts obtained by the sale of the tickets are recorded, simultaneously with the printing, automatically on the controlling strips, one of which, as stated, is inaccessible to the employee. Moreover each time a ticket is printed a counter automatically advances one. This number appears on the ticket as well as on the two controlling strips. At the beginning as well as at the end of the time he is on duty, the clerk has to print a controlling ticket

which he adds to his accounts. These two tickets show how many tickets the clerk has issued.

" 2° The production of two controlling strips gives double safety. It is entirely impossible to sell a ticket out of its proper order. Not only is it a great resulting advantage to the administration, that it is protected against embezzlement and fraudulent book-keeping, but it is also one to the clerks, for the hitherto existing distrust between them is removed. The clerks consequently like to use the machine.

" 3° The strip enables the clerk to finish off his accounts in a very short time.

" 4° The booking-office window can be used continuously, as there are no complicated taking-over operations.

" 5° The accounting is simple. The figures for each day are added up every ten days and submitted together with the first controlling strip. The quarterly accounts merely consist in a summary of the ten-day accounts.

" As opposed to these advantages there are the following disadvantages: as already remarked, the cards must at present be fed into the press by hand. It is true that the cards are stored in a holder in front of the machine, conveniently placed, but this operation nevertheless takes time."

Belgium : The machine described below has been in use a short time, as an experiment; it is not yet possible to give any opinion as to its suitability.

The description is taken from a circular issued by the firm *Appareil Contrôleur*, of Paris (Rue de Chanzy, 44).

Objects of the machine :

To print and issue tickets as required by the passengers, and to check their issue; this is effected simply and quickly by one single manoevre (per ticket issued).

Advantages of the machine :

1° It is no longer necessary to prepare and stock the tickets; ticket cupboards and detail accounting also become unnecessary ;

2° The tickets are issued easily and quickly ;

3° There is an automatic and infallible control which is carried out in the simplest manner simultaneously with the issue of the tickets; it is possible to see at any moment how much cash in hand there should be; errors and embezzlements are impossible.

4° There is a considerable saving because :

a) It is no longer necessary to prepare and stock the tickets and handle them;

b) The controlling and checking is very much simplified.

General description of the machine.

The machine consists of :

1° The case which contains the mechanism, on a stand ;

2° The number of printing stamps on a endless chain for printing the tickets ;
3° A counter which records the amounts received.

Different parts of the machine :

A roll of card, on the upper part of the machine; the end of this roll is fed in to the apparatus. An endless chain with printing stamps is wound off a drum, which is turned from outside by means of a handwheel. Each printing stamp has on it the lettering required for one ticket (date, booking station, destination station, class, kind, fare, special number of ticket). On a list of stations (with the different kinds of tickets for each station : full fare, half fare, soldiers', return) there is a movable index finger, which at the same time moves the printing stamp chain. When the ticket is printed, all the particulars necessary for the control are printed on a controlling strip. A counter (totalizer) shows at any moment how many tickets have been issued by the machine. Another counter records each fare and adds it to the amount already received. All that is necessary is to read this amount off on a disk. Finally there is a special mechanism which enables one, as often as one desires, to record on a statistical strip the number of tickets previously printed by each printing stamp together with the destination station and the fare; this operation takes 3 minutes and corresponds to the complicated accounts the clerk has to draw up when using stocks of ready-printed tickets.

Manipulation of the machine.

Press on the lever to move the drum on which the endless chain carrying the printing stamps runs ; turn the handwheel and thus set the index finger of the station list to the name and kind of ticket wanted. Then the lever is released; the drum is again at rest and the printing stam required is in the correct position. A second lever is pressed down as far as it will go and again released. The ticket desired appears on a tray fixed to the front of the machine. The following operations have taken place simultaneously :

1° All data concerning the ticket have been printed on to the controlling strip ;
2° The special counter (inside the machine) for the printing stamps has avanced one.
3° The totalizer has advanced one;
4° The disk of the counter shows the amount of the fare.

Theoretically a chain can carry any desired number of printing stamps ; practically however the number may scarcely exceed 100 (200 in the case of a double apparatus), for reasons of weight and space. If more than 80 printing stamps are on one chain, an opening must be made in the floor under the stand (20 centimetres [7 $^{7}/_{8}$ inches]) for every 10 printing stamps).

France. — *Paris-Lyons-Mediterranean Railway :* Machines of this kind have been put up at one of our stations, but as yet not enough experience is available. It is the same " *appareil contrôleur* " described above. — *French Northern Railway* : " Appareils contrôleurs " are used, experimentally, at Paris and Enghien.

As regards the machine used on the Paris Metropolitan Railway, for printing and checking tickets, I would refer to the description published in the *Bulletin of the Railway Congress* (1). These machines were also supplied by the firm " Appareil contrôleur " of Paris.

Holland. — *Dutch Railway Company :* We possess " appareils contrôleurs " supplied by the makers in Paris (rue de Chanzy, 44). The machine works well; except that there were some irregularities which were soon remedied.

I have refrained from giving any illustrations of these machines, as they are as yet chiefly used experimentally.

Question 15. — *Have your tickets on them any special mark for protection against fraudulent imitation, and if so what does the mark consist of?*

In the following countries the tickets have no special marks :

England, Egypt, South Africa, Australia.

On the other hand, the dry stamp of the administration is impressed on all tickets in Bulgaria, Norway, Austria-Hungary and Rumania.

In Germany, Denmark, Holland, Sweden and Switzerland most of the administrations impress all tickets, except the Edmonson card tickets, with the dry stamp of the administration.

Belgium : The paper tickets (book tickets), circular-tour tickets, season tickets), are impressed with the dry stamp of the State.

France : The card tickets are often impressed with the dry stamp; also the order number of the destination is frequently printed on. On the French Northern Railway, the tickets other than the Edmonson tickets often have special marks.

Italy : The card tickets have on the front face a fine network printed on, which makes any alteration, such as erasure, etc., impossible. The paper tickets are impressed, before they are sent from the head office to the stations, with the dry stamp of the administration.

Russia : The card tickets are impressed with the dry stamp, and have on them an arabesque network difficult to imitate (Orloff mark) printed in the colour selected

---

(1) No. 5, May, 1907, p. 539.

for each class, and with the numbers 1, 2, 3, corresponding to that class. The paper tickets have watermarks.

Spain : Special marks on tickets are only used in special cases, for instance feast trains, pilgrim trains, etc.; they consist of a chain, a dagger, a star, etc. In the case of a joint service the mark " combinado " is used, which is printed in the Morse code on the back of the tickets.

United States of America : The tickets are generally printed on safety paper, which is generally made specially in order to prevent fraud and alteration by acids, etc.; it is supplied by certain paper manufacturers to the ticket-printing firms, who give a written guarantee that they will use this paper for printing railway tickets and for no other purpose. Otherwise part of the paper tickets have no special mark; part of them bear an emblem, the trade-mark of the company, or have as watermark the abbreviated name of the firm or company. On many lines the tickets, also the Edmonson card tickets, have on them the fac-simile of the signature of the general manager of the company.

Argentine Republic : Great Southern Railway. — The tickets are lithographed ; the initials of the company form the protective mark.

Mexico : Safety paper is used for the coupon tickets (see United States of America).

India : The initials of the railway are on the back of the card tickets. In some cases each series of 10,000 tickets is marked A, B, etc.; and in addition the month and the year in which they have been printed is stated. If more than one series is used, each series is designated by a number placed before the letter, *e. g.*, 1 A, 1 B, etc.

CONCLUSIONS.

1° The card ticket known as the Edmonson ticket is still the one most used by all administrations, for single and for return journeys. It is named after Thomas Edmonson, who was born in Lancaster (England) 30 June 1792, and in 1836 became station master on the Newcastle-Carlisle line, where he gradually worked out a machine for printing small card tickets. Later on he became a director of the Manchester and Leeds Railway. As these small card tickets exhibited manifest advantages (*e. g.*, simpler accounting, easier checking, convenient for the passenger) as compared with the written-out paper tickets which were used in the early days of railways, which were generally of the pattern used for posting, they were very soon used not only in England but on the other railways generally.

In the case of longer journeys, particularly if several administrations are concerned, book tickets made up in various combinations, of a uniform pattern, are frequently used. Such book tickets are of very great importance as far as European travel is concerned, for the railways in Germany, Belgium, Bulgaria, Denmark, Finland, France, Italy, Luxemburg, Holland, Norway, Austria-Hungary, Rumania, Sweden, Switzerland, Servia, the Oriental railways and the Warsaw-Vienna Railway, as well as several shipping companies, adopted this system.

Thus there is, very extensively, a standard form of ticket, and in many countries this also extends to the colour of the tickets (for instance in Germany, Belgium, Denmark, France, Austria-Hungary, Norway, Sweden, Switzerland and Spain : first class, yellow; second class, green; third class, brown).

Such a standardization of the ordinary tickets, taking into consideration the fact that traffic is continually extending over longer distances, is very desirable, in the interest of the passengers as well as in that of the railway administrations.

2° There is also in many cases an agreement about tickets as regards regular journeys within given periods of time, inasmuch as season tickets enabling the holder to journey at will on given sections are nearly everywhere issued. The form and shape of these tickets varies (card ticket of larger size than the Edmonson ticket, or in the shape of a book; with many administrations the photograph of the holder has to be stuck on the ticket), but this is not of much importance, as it is generally a question of journeys within the limits of the system of one single administration. In many cases tickets are issued for a given number of journeys on one section; each journey either a hole is punched in at a determined point or else a piece is removed.

3° At the stations everywhere there are kept stocks of ready-printed tickets for all the journeys at all frequently taken; while blank tickets (*i. e.* tickets only partly printed, on which the booking clerk has to enter the name of the destination station, the fare, etc.) are only issued in cases where there is little traffic. As the issue of ready-printed tickets takes a much shorter time than that of blank tickets, the system mentioned provides for the quick booking of the passengers, but on the other hand the necessity of keeping the stations stocked with an excessively large number of different tickets is avoided.

4° The blank tickets should be designed so as to minimize errors in the accounts and frauds as much as possible. This object is attained, by most of the administrations, by retaining at the station a duplicate copy of the ticket delivered to the passenger, which is kept at the station, and then submitted, together with the accounts, to the controlling office. The latter also receives the tickets collected from the passengers in order to compare them with the station accounts. On some railways (particularly in Austria and in North America), the blank ticket has an additional section which is removed by the conductor at the commencement of the journey and is also sent to the controlling office.

5° As regards the manufacture of the tickets, a distinction has to be drawn

between the Edmonson card tickets and the other tickets. In many countries, the former are manufactured by the railway administrations themselves; this is easily and quickly effected by means of well-know machines. The other tickets and passes are generally obtained from private firms, as various types and shapes are in question, and it would be troublesome and expensive for the railway administrations to print them themselves.

6° Quite recently, several administrations also use machines which enable the booking-clerk himself to print the tickets when issuing them, and which at the same time check the tickets printed. If these experiments are successful, there will probably be a revolution in the ticket-issuing system, attended with considerable economy, although it is probable these machines will only be used for the home stations of the administrations, on account of the settlement of accounts with other administrations. This system would save, in the first place, all the wages of the ticket printers, and the complicated and lengthy ticket accounts of the station would be simplified very materially (as an instance, we may mention that at one of the booking offices of the chief station at Stuttgart there are at present 1,736 different kinds of ready-printed tickets and 270 kinds of other tickets). The ticket cupboards which take up much room at large stations would to a great extent become unnecessary. The same booking-office windows, if only used for the sale of tickets which can be printed by the machine, could be used without interruption, as there are no complicated taking-over operations when another clerk comes on duty.

As owing to their high cost, these machines can only come into consideration in the case of stations with much traffic, a necessary requirement is that the printing and issuing of the ticket should be as quick as the issuing of the present ready-printed tickets.

Taking into consideration the importance of the question, I wish to propose that the administrations which own such machines should publish the results obtained, when their experiments have been completed, in the *Bulletin of the International Railway Congress.*

7° In the greater number of countries, special tickets are issued for admission to the station (in many cases only at the larger stations), available either for one admission or for continued admission, at a fixed charge. The ticket entitling to one single admission is, with hardly an exception, shaped as an Edmonson ticket.

SECTIONAL DISCUSSION

Meeting held on 8 July 1910 (afternoon).

MR. DIETLER, IN THE CHAIR.

The President. (In French.) — Mr. von Zluhan will address the meeting.

Mr. von Zluhan, *reporter.* (In German.) — The printed report which you have before you was not drawn up by me, but by Mr. von Stierlin, who has since been carried off by a sudden illness. Mr. von Stierlin has drawn up his report with much zeal and industry; I feel that I must pay him that homage here.

I will in the first place give you a summary of this report, which in fifteen sections investigates :

The nature of the tickets;

The object of the different kinds;

The use of tickets supplied ready printed to the booking office; or

The use of blank tickets to be filled up or altered somewhat by the clerk in charge;

Measures to reduce the number of tickets.

A special paragraph deals with tickets for admission to stations.

Other sections are devoted to the question of the manufacture of tickets and to the machines used for this purpose (ticket-printing machines).

Finally, the report considers the important subject of the precautions necessary to prevent the forging of tickets.

The conclusions of the report are summed up in seven clauses, given on the last three pages of the report.

Now to begin with the question of the nature of the tickets used by the different administrations, I will draw your attention to the collection in eight volumes which are on the table for your inspection. In those eight volumes you will find specimens of the tickets issued by most of the great European railways, by some of the railways in British India, in Africa (Egypt), in Australia, in the United States, in Canada, in Mexico and in the Argentine Republic.

The last volume, the eighth, is a collection of platform tickets.

Thanks to the obliging kindness of many administrations, the reporter succeeded in drawing up a complete account of the different requirements which have to be satisfied and of the means employed to meet those requirements.

That the small Wurtemberg administration comes first, is because its collection is beyond doubt the most complete; hence

*

this apparent incorrectness which I hope you will kindly excuse.

As you know, railway tickets had as their prototype stage-coach tickets; the names and destinations of stage-coach travellers were written by hand on paper forms and lists of passengers were written out; in some cases careful identification by means of passports issued by the authorities was insisted on.

This complicated system could not be kept up in presence of the increased traffic.

Another and simpler means had to be found for the hundreds of thousands of people who wanted to travel. This method which is suitable when the number of travellers is great, is the Edmonson system which has as yet not been excelled.

Thomas Edmonson was born 30 June 1792 at Lancaster; after working for some time in a furniture factory, he entered in 1836 the service of the Newcastle-Carlisle Railway which had just been opened, in the capacity of station-master at Milton, a small station on that railway. He was the inventor of the system which bears his name and of the cupboards and dating presses used with these tickets. Thanks to his system, his name is almost as universally known as that of his illustrious compatriot and contemporary, Sir Rowland Hill, the postal reformer.

Passenger tickets have the object, on the one hand, of supplying the railway with a simple and sure means for keeping accounts; on the other hand, of supplying the public with a convenient document showing their right to travel, in all the various cases, and forming a receipt for the fare paid. This double problem was solved in a really ingenious fashion, by the use of a small ticket made of card.

Printed indications and the use of different colours are the chief means by which it is attempted to solve this problem. The simplest is, of course, that all the purposes for which the ticket is to serve should be indicated by a printed text. Thus we find on the tickets of nearly all administrations the information prescribed by the tariffs and the regulations, concerning the departure and arrival stations, the fare, the class. In addition there is often information as to stop-overs at intermediate points, for how long the ticket is available, that the ticket must not be sold or transferred, as to choice of route (railways and waterways), allowance of free luggage if any, customs examination. Besides the fare, some administrations also give the distance from departure to arrival station.

In order to check the time when the ticket has expired, the ticket is stamped, by means of a dating press, with the date of issue, unless that date can be recognized otherwise.

If the international convention for the carriage of passengers, which is now under consideration, comes into force, there will be uniform prescriptions, as regards these indications, on a large number of the European railways.

Book-keeping and accounting are facilitated by the consecutive numbers on the tickets which make it possible, in a very simple way :

1° To check how many tickets the printers have delivered to the booking offices, and consequently the value represented by the tickets the latter have received;

2° To ascertain quickly how many tickets

are left in the ticket cupboards and how many have been issued; also the sums received for the latter;

3° To check subsequently the tickets issued by the booking office and the sums accordingly paid in by the booking clerk.

If it is necessary to supply different booking offices at one station with sets of special tickets, the latter have, besides the checking number, distinctive marks, numbers or letters.

Similarly the tickets issued by agents and by automatic machines have special marks.

Besides the information printed on the tickets, it has been recognized necessary and rational, both in order to accelerate the work of issue and the checking, and to make matters simpler for the public, to differentiate the tickets and the covers of book tickets by using paper of different colours in their manufacture. From this point of view, it is useful to make definite differences between tickets for the different classes, as well as between those available for ordinary and for express trains. The detailed enumeration of all the arrangements adopted would be too long for my summary; the systems adopted by the different administrations vary too much with the tariffs and the services.

With many of the administrations, in Germany for instance, for the book tickets of the international Union and the book tickets known as agents' tickets for journeys in Europe, the colours adopted are as follows :

First class tickets	Yellow.
Second — —	Green.
Third — —	Buff.

In the case of Edmonson tickets for the fourth class, grey paper is used in Germany.

In some cases the colours of the tickets correspond to those of the outside of the passenger carriages.

Tickets available for all trains often have a red line printed across them. Double tickets, formed of two parts, for instance for an outward journey and a return journey, used for successive journeys in carriages of different classes, have the two halves made of different colours.

One also finds tickets of two colours divided diagonally; for instance children's tickets and soldiers' tickets. In addition our collection includes : tickets with two, three or four lines of different colours printed on them, in some cases parallel to the long side, in other parallel to the short side, sometimes on the outer edge (bordered), or in a corner or in the middle of the tickets; tickets with several lines which cross each other, with dots, with large coloured marks or with very visible marks, so that a nearly inexhaustible number of varieties exist.

Shape of the tickets.—As I have already remarked, the most ordinary shape adopted for tickets is the Edmonson shape, with dimensions of 57 × 30·5 millimetres ($2\ ^1/_4 \times 1\ ^3/_{16}$ inches).

Of course those dimensions are not always adhered to; it is often useful, in the interests of the service, to exceed them, for reproducing tariff regulations, for checking purposes and also in the cases of workmen's tickets, season tickets, mileage tickets, tickets for special trains, etc.

Tickets which are available at will over different routes or by different means of carriage have coupons attached which can

be detached by the employees so as to facilitate the accounting work.

Paper tickets. — Tickets which are available over lines belonging to several different administrations are also made of paper, with coupons for the different lines which are going to be used; these are either books with fixed destinations, for use between two definite stations, or else books made up of selected tickets (circular tickets). In this connection, I may mention the organization of international travel, adopted by a certain number of the great railways of Europe (Switzerland, France, Italy, Belgium, Holland, Germany, Denmark, Sweden, Norway, Austria, Hungary and Bulgaria). Books of this kind often contain print in German, in French and in Italian. Tickets with prints in different languages are also found in the internal service of some railways, for instance in Belgium, in India, in Egypt.

Book tickets are also included among the tickets issued by travelling agencies, to whom the railways hand against payment the tickets (paper tickets) they require; the latter then put them together to suit the travellers. As an instance I will quote the Cook's book tickets, which are very generally known.

Among tickets of exceptional shapes which figure in our collection, I may mention : octagonal tickets in France, in South Africa and in Australia (simple and double), oval tickets in France and in Australia.

Besides paper and card, the following materials are also used for tickets : linen for season tickets, and for tickets generally which are going to be used for a more or less considerable period of time; then leather for season tickets in England, in France, in Austria, in Hungary and in Australia.

Trials made quite recently by several directorates of the Prussian State Railway with Edmonson tickets made of thin card, have shown that this is not to be recommended; the saving of about 1·6 per cent in the cost of the card is counterbalanced by the greater cost of printing on the existing machines.

In Australia season tickets consist of metal disks (silver or gold) of oval or circular shape, which can be hung from a watch-chain. The section for which the ticket is available is indicated by letters or numbers.

Classified by class of train and of carriage, there are tickets for ordinary trains, express trains, "*trains de luxe*", special trains of all kinds, tickets for Pullman cars in the United States, sleeping-car tickets, sleeping-berth tickets, reserved-seat tickets.

In order not to overload the stations with excessive supplies of tickets, supplementary tickets (zone tickets) are issued, which taken together with tickets for ordinary trains entitle the travellers to go by express trains or by a higher class. There are excess tickets for the additional charges which have to be paid by passengers having tickets which do not go far enough, or which are for classes and trains for which the tickets are not available, or by passengers who have no tickets.

Our collection altogether contains three chief kinds of tickets :

1° Tickets for a journey over a given route (single tickets, return tickets, simple circular tickets);

2° Tickets available for several journeys over a given route, namely :

a) For a given number of journeys, books with detachable coupons for ten, twenty, thirty or more journeys, or cards with dates printed along the border, the date being marked by punching or otherwise when a journey is taken ; workmen's tickets (week tickets) which can utilized twice a day or twice a week ; pupil tickets available on certain week days or by certain trains ;

b) For travelling at will on a given section during a given time ; season tickets for a week, a fortnight, a month, a quarter, a year. Among these we can also class the season tickets known as general, for travelling on all the lines of a whole railway system for a given length of time, in Switzerland, in Denmark ;

3° Mileage tickets, on a differential basis, used especially in Switzerland, in the United States, in South Africa and in Russia, usually at a reduced rate ; they can sometimes be utilized by the members of a firm or of a family, during a given period of time. As a general rule, they are used for exchanging at the booking office for a ticket for a single journey, of so many miles, to a given point on the line.

In order to promote sport, health and especially also excursions for the populations of large towns, there are issued : tourist tickets, Sunday tickets, bicyclists' tickets ; holiday, summer, season tickets ; tickets to watering places ; school excursion tickets and family excursion tickets ; week-end tickets for going out of town and returning, stopping over Sundays and also feast days, tickets for going to horse races.

Special tickets, as a rule at reduced fares, are issued : to passengers who are not adults (children from 4 to 10 or from 10 to 12 years of age), for pupils, for workmen, for members of the armed forces (lower grades of the army and navy), then for commercial travellers, for engineers, for emigrants, for pilgrims (Switzerland, India), then, in India, for servants.

I, finally, have to mention the tickets for charitable purposes generally (care of the sick). Nor let us forget the tickets for man's faithful companion, namely dog tickets.

As I have already stated, it is impossible to enter into the details of the various peculiarities of the tariffs and regulations which have to be considered in connection with the different kinds of tickets.

I must content myself with having given you a summary account of the varied conditions which have to be considered in connection with passenger traffic and the tariff policy of railways.

Blank tickets. — Seeing the great number of relations between stations (for instance Anhalt Station at Berlin has 47,000 different tickets) and the many needs of the traffic, it is not possible to supply booking offices with ready-printed tickets for all the stations of a railway or of an association of railways and for all cases which may arise. It is hence indispensable to limit the number of the tickets. Among such measures we may mention the use of blank tickets for several passengers (tickets for societies, to be filled up by hand), then the issue of collective tickets, having printed on them the name of several stations for any one of which the ticket is available. These tickets assume that the fare is the same for all the distances or stations considered. Smaller

differences of distance between stations can be neglected.

An effective means for reducing the number of tickets and supplies necessary at stations, a means adopted by most of the administrations, consists in the use of blank tickets. In this case, part of the indications which are printed on the ordinary definite destination tickets are entered by hand or by some mechanical method, by the booking clerk in each individual case. They are more especially: in cases of little traffic between two stations, where it does not seem necessary to provide a stock of completely-printed tickets; in case of unforeseen exhaustion of the stock of definite-destination tickets; for excess charges, for instance in cases of involuntary or intentional change of class, or of continuation of the journey beyond the point the ticket is available to. Some administrations use blank tickets of a shape and appearance similar to that of ordinary Edmonson tickets. Other administrations use blocks of blank tickets made of paper. As a rule, blank tickets are less satisfactory than definite-destination tickets from the point of view of book-keeping and of checking the accounts. It is a little more difficult to check the tickets on the trains and at the platform entrances; the employees can more easily go in for frauds. Various measures have been taken to obviate these disadvantages. In the first place endeavours are made to reduce to a minimum the particulars which have to be filled in or added, especially as concerns the fares. Those parts of the blank tickets on which the entries have to be made are sometimes arranged so that any ultimate alterations by erasure, etc., becomes impossible. Moreover, the tickets bear printed consecutive numbers for checking purposes.

The blank tickets are issued at the station from duplicate books, the original being kept at the station for checking purposes; or else the blank ticket has a section which has to be filled in like the ticket delivered to the passenger.

In writing on the blank tickets, it is advisable to use hard pencils, so that the writing may be legible. The counterfoil and the ticket must have the date stamp impressed on them.

In some countries, in Italy for instance I think, an ingenious attempt has been made to check the blank tickets to some extent by forming them of two coupons which have the price printed on (in francs). At the time of issue, the employee cuts the ticket so that the coupon remaining at the stations for book-keeping purposes indicates, in francs, the same sum as the coupon given to the passenger.

In Rumania, the blank tickets consist of two Edmonson tickets joined together, showing the name of the issuing station and also the price of the ticket in francs (from 1 to 60 francs [10*d.* to £2.8*s.*]). The booking clerk has only to enter the class, the destination stations and the centimes. One of the tickets is detached by the booking clerk and serves as check.

On certain of the lines in India there are blank tickets, with indication of price, for different distances (up to 100, up to 250, up to and beyond 500 miles).

As against the disadvantages inherent in blank tickets, one must mention as advantages, firstly, the already-mentioned possibility of reducing the number of ready-printed tickets, the possibility of using one and the same ticket for several

passengers, finally, and above all, the advantage of the through booking of passengers and luggage to all stations to which definite fares either exist or can be worked out by the clerk. The rules adopted by the the different administrations as to the importance of the traffic for which ready-printed tickets are issued, even as regards the case of an association, differ widely, as you will see from the report you have before you : it varies between 4 and 600 tickets per year.

Platform tickets. — The question of the need of special tickets for admission into the stations, when it is not a question of tickets proper, has received a different solution according to whether the administration closed the stations completely or partially. The system of closed stations can in the first place recommend itself owing to general reasons, firstly, in order to make the platform accessible to passengers and secondly in order to remove other people, in the interests of the service. The platform must not form a promenade for the public. The need of such a measure is especially apparent in the case of stations in towns and in that of busy stations generally. On the other hand, the institution of special tickets for admission to the platforms becomes necessary when the tickets are checked not on the train itself, but at the entrance of the departure station and at the exit of the arrival station. In this case the tickets of the passengers who go on to or leave the platforms must be carefully checked.

According to the report we have before us, the complete closing of the station only exists, and special tickets for admission to the platforms, as a general rule, are only required in Germany, in Belgium, in Bulgaria, in Italy, in Austria, in Hungary, and in Egypt, A mixed system, including special tickets only for admission to stations of a certain importance, has been adopted in Denmark, England, France, Holland, Norway, Rumania and Sweden, as well as by the Indian and Australian railways, and in very rare cases, by railways in the United States. The other countries, especially Switzerland, do not have platform tickets or only issue them to hotel servants.

In the collection of tickets submitted to your examination, a special volume contains specimens of the platform tickets issued by a certain number of administrations. Nearly all the administrations which have adopted the system of platform tickets issue tickets giving right to one single admission. These tickets are usually of the Edmonson type; there seems to be a predilection for selecting conspicuous colours and marks, easy to distinguish from those of the ordinary tickets. Some administrations limit the time of validity of the tickets to a certain number of hours (from one to two hours). These administrations use tickets on which the number of hours for which they are valid are printed, and the tickets are punched when entering and when leaving. Sometimes the platform tickets bear the inscription : " Not available for admission to carriages. " Some administrations, Denmark, for instance, use a system of double tickets, analogous to return tickets.

The cost of a ticket entitling the holder to *one single* admission generally varies between 5 and 25 centimes (between $^1/_2$ *d.* and 2 $^1/_2$ *d.*). The issue of these tickets by means of automatic machines seems a rational proceeding.

The collection of specimens, which is before us, shows that the administrations of the railways in Denmark, Holland, Italy, Austria, Hungary, Norway, Spain, British India and Australia issue tickets for a number of admissions : monthly tickets, quarterly tickets, half-yearly tickets, yearly tickets. Such tickets are not generally of the Edmonson type, but in book form or other special form. Their cost varies considerably. In Italy a scale of rates has been made according to station, whether first or second class, for 20, 40 or 80 admissions; these tickets have small coupons, one of which is detached at every admission.

The question of granting free access to certain persons, not holding platform tickets, to the reserved parts of the stations, for reasons of public or of business interest, has been solved in different ways on different railways. While some administrations only allow admission generally to the holders of tickets they have paid for, others make exceptions for reasons of a public kind, for instance in favour of legal and court officials, of police and of sanitary officials, of delegates of the committee for preventing the white-slave traffic, etc.

Certain administrations, for instance most of the German railways, refuse in principle to treat hotel servants on another basis than the general public; other administrations on the contrary grant free admission to these servants.

Manufacture of the tickets. — The methods of manufacturing the tickets vary with the different administrations; some think it advisable to have their own printing establishments, others do not. Most of the administrations manufacture at least the greater part of their tickets, the Edmonson tickets, in their own printing establishments and only obtain from private firms the paper tickets (book tickets for definite journeys and leaves for making up into books), the strip tickets and the season tickets. Few administrations print paper tickets themselves. The railways in the United States and in Mexico as a rule order their tickets from printing firms.

The printing machines used as supplied more especially by the firms Ravasse, of Paris; Waterlow & Sons, of London; and *Gandenbergersche Maschinenfabrik Georg Göbel,* of Darmstadt. Some of these machines can also be used for printing tickets of a size larger than that of Edmonson tickets, for instance 70 × 46 and 135 × 65 millimetres ($2\ ^3/_4 \times 1\ ^{13}/_{16}$ and $5\ ^5/_{16} \times 2\ ^9/_{16}$ inches).

I may be allowed to refrain from giving details of these machines. I will limit myself to mentioning the following points: most of the administrations use printing machines with electric motor. Often automatic counters are added to them. Some administrations have special counting machines. Other do not use these, particularly in the case of printing machines with electric motor; they are satisfied with the accuracy of the latter.

The tickets are generally put together in packets of one hundred tickets. Sometimes the packets have on the side a black line or mark which makes it possible to see at once if a ticket has been taken out of the packet. For some time trials have been made to count the tickets and put them together in packets automatically.

At the stations the tickets are got ready for issue by placing them in special cup-

boards, arranged in two ways; sometimes they are placed one on the other so that the lowest number is at the bottom; sometimes they are placed upright, with the lowest number in front. A system has now been in use for some time in which the tickets are printed on strips which are rolled up. The different tickets are separated by perforations and hence can be easily detached. The object of this system is to prevent intermediate tickets from being fraudulently removed. A ticket cupboard of this kind is exhibited, if I am not mistaken, in the German railway section at the Brussels exhibition, by the Berlin Company *Deutsches Post- und Eisenbahnverkehrswesen*. According to a note recently published in the *Zeitung des Vereins*, the Austrian State Railway has also lately undertaken trials with tickets in rolls.

Automatic ticket machines. — The tendency, in all branches of work, of replacing human labour by mechanism has led in recent years to the construction of ingenious machines for the sale of tickets. I speak of the automatic ticket-supplying machines, available for the use of the public. Originally designed to meet very simple conditions, they have recently been considerably improved. They are more especially useful in the case of services between adjoining stations, and in that of suburban services.

Machines for printing tickets as and when required. — On page 20 of the printed report (1) you will find the results of the inquiries into the use of machines by means of which tickets are printed by the booking clerk and checked, as and when required. It is unnecessary for me to urge the great utility of these machines, provided they are suitably designed and work so as to safeguard the pecuniary interests of the administrations. The stock of tickets in the booking office can be materially reduced, and accounting and checking operations can be much simplified if the machines are equipped with self-contained checking apparatus. At the time the printed report was drawn up, machines of this kind were in use only in Belgium, in France, in Holland and in Germany. I do not know with certainty whether matters are changed now; but I think I may assume this to be the case. At least I have been told that the English machine, used by German railway administrations, has been ordered extensively. The Belgian State Railway has kindly informed me recently that its " *appareil contrôleur* " (Paris, rue Chanzy) has not yet given results sufficiently definite to enable the administration to decide to adopt it in practice; that the printing press proper works well enough, but that the counters leave something to be desired, probably because the actual operation, being by hand, is a little uncertain; that electric motors are going to be fitted and that new trials are going to be made.

The administration of the French Northern Railway has been good enough to write to me, annexing a number of the *Revue générale des chemins de fer* for 1904, that the " *appareil contrôleur* " has been recently improved and that it intends to make trials with a new apparatus exhibited at Brussels, with an automatic counter. The Paris-Lyons-Mediterranean Railway is satisfied with this machine.

(1) See also *Bulletin of the Railway Congress*, December 1909, p. 1786.

In Germany, according to my inquiries, such good results have been obtained with the printing machine suppied by the firm Felten & Guillaume Lahmeyer of Francfort on the Maine, in use at Cologne and also at Essen, Mayence and Strasburg, that the administration of the Prussian State Railway is, it seems, considering the advisability of using it on a large scale. I have asked that one of these machines should be sent here so that I might show it to you. The manufacturer has also placed at my disposal a number of prospectuses, etc., which I have placed on the table.

Just as in the case of the automatic distributing machines, I do not propose to give a long description of this ingenious and complicated machine. I will merely mention that with a machine of this kind it is possible to print up to 2,000 different tickets, and even more, at the time they are issued, by simple operation of a lever, without delaying the passenger, even if the work is carried out by women; and that the tickets are at the same time recorded on two check slips, one for the use of the clerk when making up his accounts, while the other, which the clerk cannot get at, is intended for checking purposes. Besides the firm mentioned above, it seems that the *Gandenbergersche Maschinenfabrik G. Göbel*, of Darmstadt, is also engaged in constructing machines of this kind. This firm has also sent us a certain number of illustrations and descriptions of their machines for producing tickets.

Precautions against forgery. — Owing to the occasionally high price of tickets, there is naturally a temptation to put into circulation, to the detriment of the administration, forged tickets, with or without the connivance of the railway employees.

It hence seems advisable to have special marks on the tickets as a protection against forgery. With this object in view, some of the administrations impress their tickets with a dry stamp, either both the card and the paper tickets, or at least the paper tickets (books for definite journeys or made-up books). In France, as an extra safeguard, the tickets have printed on them the number of the station. In Italy and Russia a fine network is printed on the face of the tickets, so as to prevent any erasures and alterations. In Russia a special network is used. Several railways in the United States and in Mexico use paper specially made for the purpose. Other precautions consist in having on the tickets the trade-mark of the company or the initials of the company or the facsimile of the signature of the general manager of the company. Some administrations, for instance those in Great Britain, in Australia, in Egypt and in South Africa, use no special marks.

Free passes. — Gentlemen, I should be guilty of ingratitude if, to finish up with, I said nothing about a variety of tickets particularly dear to many of us and fully appreciated : I mean the free passes which have enabled us to come here and meet for our joint labours. I have made no special study of this subject, nor have I made a collection of specimens. You all know the subject from your own personal experience. You also fully appreciate the international exchange of these free passes by which our employees largely benefit during their leave, and in case of illness and other cases.

These passes are generally of paper or of parchment. There are also, for in-

stance in England, metal passes of very solid make and rather heavy. But those entitled to use them carry them certainly quite as readily as our lighter passes. No doubt, in our organization there is lacking one thing which makes it less complete than the free passes (*tractoria*) of the Roman and Frankish posts which granted, in addition to free conveyance, hospitable cheer at the stopping places, in accordance with the rank of the traveller, and that on a very liberal scale. We can hardly develop our free-pass system to this extent and I accordingly think I can end, without proposing any conclusions on this point, by expressing our best thanks to the hospitable Swiss administrations for the amiable way in which they have received us and our companions, and for the liberality with which they have given us free conveyance on all the lines in beautiful Switzerland.

As I have already stated, the conclusions relating to the subject which we are considering are given on the last three pages of the report. I will yet draw attention to the following points :

1° Up till now, the Edmonson ticket is the one most used. However, is seems advisable to try to modify this system so that the tickets can be detached from rolls placed in special apparatus.

With this method of dividing up the tickets, the checking would clearly be much facilitated ; it is less easy fraudulently to remove intermediate tickets.

When conditions are a little more complicated, it is indispensable to use paper tickets also ;

2° Blank tickets form an effective means of reducing the excessive number of tickets. In order to satisfy requirements, it must be easy to fill them in, they must be legible, and the means of checking them must be such as to prevent fraud ;

3° The use of mechanical apparatus, in order to relieve ticket-printing establishments and clerks at booking offices, should be extended as much as possible. More especially should great attention be given to the use of ticket-printing machines at the booking offices of large stations. The results of such experiments made by the administrations should be published in the *Bulletin of the Congress*. (*Applause.*)

The President. (In French.) — I shall no doubt express the opinion of the whole meeting by thanking Mr. von Zluhan for the excellent summary he has just given us. (*Applause.*)

Mr. Minet, Belgian State Railway. (In French.) — The regulations state that any one speaker should not speak for more than half an hour. Now the reporter has spoken for nearly an hour, while presenting the summary of his report, which seems to contain new information which is not found in the printed report which we have before us.

Mr. von Zluhan. (In German.) — I have read my summary very slowly so as to make myself more intelligible to those who do not understand German well. Moreover, I have had to allow for the fact that the report was printed more than a year ago. In the meantime, new experiments have been made with printing machines ; it was accordingly necessary to deal with this point more in detail and mention the new inventions.

Mr. Brandt, Dutch State Railway. (In French.) — The difference between Mr. von

Zluhan's conclusions and those of Mr. von Stierlin relate chiefly to the use of printing machines at the booking offices of large stations. Numerous experiments have been made during the last few months, in France and in Belgium, with a machine for printing the tickets.

The President. (In French.) — The Regina ticket-printing machine, made by the firm Felten & Guillaume Lahmeyer, of Francfort on the Maine, has just arrived. I invite the members of the 3rd section to go into the adjoining room in order to examine this machine.

— The meeting adjourned 3.18 p. m. and met again at 3.55 p. m.

The President. (In German.) — We resume the discussion of question XI.

I call upon Mr. Domsch.

Mr. Domsch, Saxon State Railway. (In German.) — Among the explanations given by the reporter, no doubt the greatest interest centered in those about the ticket-printing machine, the Regina machine shown to us. In fact this is an apparatus which can, in suitable cases, lead us to transform to a certain extent the ticket service. From this point of view, great importance must be attached to the fact that the new German machines make it possible to use a large number of different printing stamps, whereas with the old "*appareil contrôleur*" this number was limited to one hundred. The essential difference is that with the "*appareil contrôleur*", at least with the type which I know, all the printing stamps have to be shifted, together with the chain carrying them. The work the clerk has to do accordingly becomes more onerous as the printing-stamp chain becomes heavier. With the Regina machine, supplied by the firms Felten & Guillaume Lahmeyer, on the contrary, each printing plate comes out of the holders and is raised to the printing table; and after the printing the plate is replaced in its original positions. Hence, it follows that a much larger number of plates can be used with the Regina machine. As we have already been told, up to 2,000 plates can be used with it.

The reporter has already mentioned the great advantages of the ticket-printing machine from the point of view of the saving in printing, the stock of tickets, the book-keeping and even the booking-office service, under varying conditions; it is true that up till now it is only a question of experiments and that as yet no definite opinion can be given of this machine. But it already seems certain to me that the ticket-printing machines can only be used at stations where there are several booking offices; at a station with one single machine, this might break down and one no longer would be able to use a neighbouring machine.

What I have just said shows that it would be wrong to try to improve the ticket service only by trying to find a good ticket-printing machine. It should also be tried to make innovations tending to simplifications and economies in making, storing and issuing tickets. A well-organized railway administration is bound to pay every attention to this department, however secondary it may seem as compared with others. Accordingly the administration to which I belong, and other German administrations also, some time ago began numerous experiments

which it perhaps would be advisable to enumerate here, although the reporter has already said a word about them.

These experiments relate to the following points :

1° *The use of a cheaper card for the Edmonson tichets.* — Now that return tickets are nearly wholly abolished in Germany and that the validity of single tickets is four days, the tickets remain such a short time in the hands of the passengers that one can use card which is, if not thinner, at least of poorer quality and consequently cheaper than that at present used by many of the administrations. But the quality of the card must not be so poor that the ticket-printing presses are affected. At present my administration feels convinced that this modification will in the long run enable it to effect appreciable economies.

2° *The use of thinner card, particularly in the case of local and suburban traffic.* — For the local and suburban traffic, where the tickets do not remain tn the possession of the passenger for more than an hour or two, thin and flexible card may sometimes be used, which is still cheaper than that just mentioned. It must however not be too thin to receive the imprint of the date, whether by the dating machine or by the hand stamp of the clerk.

This experiment is at present being carried on and my administration can as yet give no opinion about the results.

3° *Tickets in rolls.* — The use of thin card makes it possible to print the tickets and store them in rolls, without cutting them apart beforehand ; perforation makes it easy to detach the different tickets. These ticket rolls seem especially useful for use in automatic ticket-issuing machines. One is also engaged in making cupboards for ticket rolls so that each division can hold a roll of several hundred tickets and from which the clerk obtains the ticket by tearing it along the line of perforation. Experience will show whether this innovation, which is intended to prevent the removal of intermediate tickets, is advantageous and whether it will frequently give trouble. One trial has already shown that the roll easily becomes entangled. But it seems that the holders have been improved since.

4° *Tickets in blocks.* — One can also, by using card which is somewhat thin, put the tickets together in blocks of fifty, and place these blocks side by side in a cupboard designed for the purpose. This system is also under trial at present; it is thought to be convenient for small stations and for the issue of tickets by the train conductor.

5° *Automatic machines for delivering ordinary and platform tickets.* — Numerous trials have been made of new types of automatic machines for delivering ordinary and platform tickets, and some of them have already given very satisfactory results. The old machines, with which the passenger had to insert a coin, then operate a lever, etc., in order to receive a ticket which had been cut off and printed in advance, no longer suffice for the needs of large stations and one begins to give them up. The new machines have clockwork or electric gear, print the tickets, separate them from the roll and deliver them to the passenger; all the latter has to do is to introduce the coin prescribed. Such machines can also be constructed so as to work when several coins are introduced, or to give change for a coin of

higher value. Hence, they form, not only for platform tickets but also for tickets for the local and suburban services, a valuable addition to the booking-office service. The high initial outlay they represent can often be completely redeemed by the saving in the cost of printing, etc., and by the work saved the booking office clerks.

Unfortunately it is as yet hardly possible to draw any definite conclusion from any of the experiments mentioned, which are in progress, mentioned under 3°, 4° and 5° above; nor can this be done as regards the Regina machine and the patents of the German firms. It is probable that many other administrations outside Germany are making similar trials.

It would hence be a matter for congratulation if the Congress continued to devote its attention to this question and would act as intermediary for the exchange of the results obtained by the different administrations. But I will go further in this direction than the reporter, and I will propose that this exchange of information should not be limited to publication in the *Bulletin*, which would perhaps not take place till after repeated request; I would propose that we at once consider the advisability of placing the question of the improvement and the simplification of the ticket service, in the agenda of the next session of the Congress.

The President. (In German.) — Does anybody else wish to address the meeting?

The bureau only has eight copies in French and in German of Mr. von Zluhan's conclusions. Accordingly it is impossible to give one to each delegate and under these conditions it would no doubt be preferable to adjourn the discussion to tomorrow morning. At that time a sufficient number of copies of the conclusions will have been printed. I would also remark that Mr. von Zluhan's conclusions are much more concise than those printed in the report. They consist of three paragraphs and it will not take long to discuss them.

You will also have to decide about the proposal last made and to say whether you will expand one of the three clauses for this purpose or will add a new one.

Mr. de Tchérémissinoff, Permanent Commission of the Congress. (In French.) — If the President would read out the conclusions we could already begin the discussion and continue and finish it tomorrow.

The President. (In German.) — This is Mr. von Zluhan's first conclusion : " The ticket is the Edmonson type and is at present the one most used. We ought to attempt to divide the tickets in special apparatus. Moreover, the system of made-up tickets can be used."

Mr. Tondelier, *vice-president*. (In French.) — I do not quite understand the meaning of the second sentence : " We ought to attempt to divide the tickets in special apparatus."

The translation perhaps does not give the exact German meaning.

Mr. von Zluhan. (In German.) — With the new apparatus which makes it possible to detach from the roll a ticket having the same size as the Edmonson ticket, the strips of card are perforated. With the system of tickets in packets, an intermediate ticket can be removed, while this is

not possible in the case of a roll. It is advisable to make trials as to the working of these apparatus. The manufacturers mention as the chief advantage of these apparatus that the rolls prevent any swindling in the booking office.

Mr. Tondelier. (In French.) — Is the reporter wholly considering tickets made in special apparatus? Does he ask that one should try apparatus for dividing the rolled strips of paper, then to be printed on, in special machines?

Mr. von Zluhan. (In German.) — There are two classes of tickets on rolls : 1° the tickets printed by the printer which the clerk places in his cupboard ; 2° the tickets printed by a special machine. This is the automatic apparatus mentioned by Mr. Domsch from which the public or the clerk can obtain printed tickets in exchange for a coin which is introduced.

The President. (In German.) — Then we are to retain the sentence concerning attempts, so that the conclusions may cover both systems?

Mr. Domsch. (In German.) — Would it not be better to say : " It is advisable that we should make experiments with a view to improving the present form of tickets, by using, for instance, strip tickets or ticket rolls."

Mr. von Zluhan. (In German.) — I agree.

The President. (In German.) — It is a question of knowing whether we agree in principle to express the wish proposed. If so, we will draft a conclusion which we will submit to the section tomorrow morning.

Mr. Tondelier. (In French.) — The report does not mention the disadvantages of the Edmonson system. Nor does it speak of the need of improving it.

The President. (In French.) — This is the whole question. Must we look for another system?

Mr. Kareiska, *principal secretary.* (In French.) — What is the reason why the reporter wants trials made?

When the tickets are placed one on the other, they can be separated by an intermediate piece of paper.

Mr. von Zluhan. (In German.) — Gentlemen, since the printed report was issued, new inventions, I again remark, have been made, among others that of machines printing the tickets on rolls. I also stated that these machines were exhibited at Brussels. The manufacturers of the machines explain that any fraud on the part of the employees becomes impossible, the checking of the tickets being automatic. It is just the absence of this checking which is the great disadvantage of the system of having the tickets in packets. In drawing up the conclusions, I started from the point of view that it appeared advisable to make trials and collect information about the services the new systems can render.

The President. (In German.) — It is asked whether we are to add this sentence or not. I think that these trials will be carried out even if the Congress does not expressly request this. If we have any doubts as to the need of this sentence, it would perhaps be better to omit it. After all, we must only submit conclusions

which we have investigated completely and all agreed to.

Mr. Tondelier. (In French.)—We should limit ourselves to the statement that we have taken note, with much interest, of Mr. von Stierlin's report and that we express the desire that the question should be among the agenda for the next session of the Congress; the different administrations will give information about the trials which they have made with a view to improving the system of passenger tickets.

The President. (In German.) — I think with Mr. Tondelier that we may limit ourselves to thanking the reporter and to stating that the section thinks that there are still further improvements which it is possible to introduce. We would add that the administrations should continue to investigate the subject which should be placed on the agenda of the next session.

That conclusion would satisfy Mr. Domsch, and at the same time would eliminate all details, about which we find it difficult to come to a conclusion.

Mr. de Tchérémissinoff. (In French.) — The reporter has stated today that improvements have been introduced since the printing of the report.

Now these improvements are so recent that it would be preferable to wait some time for their results.

The President. (In German.) — If the meeting agrees with Mr. Tondelier, the bureau will draft a text for tomorrow morning. (*Approval.*)

Meeting held on 9 July 1910 (morning).

—

The President. (In German.) — The bureau has drafted a new text concerning passenger tickets. At the request of the reporter, we have retained clauses 2° and 3°.

This is clause 1° of the conclusions :

" The Edmonson ticket is at present the one most used. Recently machines have been constructed in which these tickets can be separated from a card roll. In special cases, however, paper tickets can not be dispensed with."

In drafting these conclusions, we have tried to co-ordinate the different proposals which were made yesterday. The conclusions have consequently become somewhat longer.

— Adopted.

The President. (In German.) — Clause 2°, runs as follows :

" Blank tickets suitably correspond to the need of limiting the excessive number of tickets. But in order to attain their object, it must be possible to make them easily and legibly, and there must be means of checking to prevent fraud."

Mr. Tondelier. (In French.) — In order to be quite clear, we should replace the words " correspond to " by the word

" satisfy ". We would then say : " Blank tickets suitably satisfy, etc."

Mr. Minet. (In French.) — What we are aiming at, is reducing the number of tickets placed in the ticket cupboards at the disposal of the clerks. I therefore propose to say :

" The use of blank tickets is justified by the need of reducing as far as possible the number of tickets in the ticket cupboards. But in order to be suitable, they must be easily filled in and be legible ; and it must be possible to check them so as to prevent fraud."

— Clause 2° thus amended is adopted.

The President. (In German.) — Clause 3° runs as follows :

" In order to relieve ticket-printing establishments and the clerks at booking offices, it is advisable to extend, as far as possible, the use of mechanical apparatus ; attention should be paid especially to the use of printing machines at the booking-office windows of large stations. The results of the experiments made by the administrations for the purpose should be communicated by means of the Congress publications."

Mr. Minet. (In French.) — I propose that the last sentence should be replaced by this wording :

" The results of such experiments made by the administrations should be published in the *Bulletin of the Congress*."

— Adopted.

The President. (In German.) — Clause 4°, which will give satisfaction to Messrs. Domsch and Tondelier, runs as follows :

" Taking into consideration the improvements and simplifications introduced since the printing of the report, in the manufacture and in the issue of tickets, and those which may be still further realized in the future, it is desirable that this subject should again be discussed at the next meeting of the Congress."

— Adopted.

The President. (In French.) — We have accordingly finished the investigation of question XI and we will submit to the general meeting the conclusions we have just adopted.

DISCUSSION AT THE GENERAL MEETING

Meeting held on 14 July 1910 (morning).

MR. P. WEISSENBACH, PRESIDENT, IN THE CHAIR.
GENERAL SECRETARY : MR. L. WEISSENBRUCH.
FIRST ASSISTANT GENERAL SECRETARY : MR. MÜRSET.
SECOND ASSISTANT GENERAL SECRETARY : DR. A. BONZON.

Mr. Kareischa, *principal secretary of the 3rd section*, read the

Report of the 3rd section.

(See *Journal quotidien de la session*, No. 7, p. 9.)

" In place of the late Mr. von Stierlin, the author of the report, Mr. VON ZLUHAN (*Wurtemberg State Railway*), gave a summary of the different systems of passenger tickets adopted by fifty-seven railway administrations in different countries. The tickets were made of card, paper, leather or metal, and were very frequently of the Edmonson pattern, or were made up into books, or other forms, in accordance with the different conditions in the tariffs. A distinction was drawn between completely-printed tickets, and blank tickets. In certain countries, it was necessary to have tickets for admission to stations; in other countries, this only applied to very large stations; finally some administrations required no tickets for admission to stations. The administrations as a rule printed the Edmonson tickets themselves, while the other tickets were obtained from private printing works. Many countries had machines for counting the tickets. At some of the large stations in Germany, in Belgium, in France and in Holland, the tickets were printed in the booking offices as and when required. In order to prevent forgery, the tickets were impressed with a dry stamp, or had network on them, or some other special marks. Mr. von Zluhan then read his conclusions, which were not quite the same as those in the report.

" The delegates then examined a Regina ticket-printing machine, manufactured by Messrs. Felten and Guillaume Lahmeyer, of Frankfort on the Maine, which was exhibited.

" Mr. DOMSCH (*Saxon State Railway*) ex-

plained the advantages of this machine; he observed however that in practice it was not suitable except for large stations. He recommended the continuation of trials of Edmonson tickets made of cheaper or of thinner card, as well as of tickets in rolls, of tickets in blocks and of automatic ticket-distributing machines. It would be desirable for the Congress to retain the question on the agenda for the next session.

" After sundry observations by Messrs. TONDELIER and MINET (*Belgian State Railway*), DOMSCH, KAREISCHA (*Russian government*), VON ZLUHAN and DE TCHÉRÉMISSINOFF (*Permanent Commission of the Congress*), the following conclusions were adopted."

The President. (In French.) — The following are the

CONCLUSIONS.

" 1° The Edmonson ticket is at present " the one most used. Recently machines " have been constructed in which these " tickets can be separated from a card roll. " In special cases however, paper tickets " cannot be dispensed with.

" 2° The use of blank tickets is justified " by the need of reducing as far as possible " the number of tickets in the ticket cupboards. But in order to be suitable, " they must be easily filled in and be " legible; and it must be possible to check " them so as to prevent fraud.

" 3° In order to relieve ticket-printing " establishments and the clerks at booking " offices, it is advisable to extend, as far as " possible, the use of mechanical apparatus; attention should be paid especially " to the use of printing machines at the " booking-office windows of large stations. " The results of such experiments made by " the administrations should be published " in the *Bulletin of the Congress*.

" 4° Taking into consideration the " improvements and simplifications introduced since the printing of the report, " in the manufacture and in the issue of " tickets, and those which may be still " further realized in the future, it is desirable that this subject should again be " discussed at the next meeting of the " Congress."

— These conclusions were confirmed by the general meeting.

SECTION III : WORKING

[621 .132.8 & 621 .33] QUESTION XII

MOTOR VEHICLES

(2nd, 3rd and 5th SECTIONS MEETING JOINTLY)

The use and cost of motor vehicles or self-moving cars.

Reporters :

Great Britain. — Mr. T. Hurry Riches, locomotive, carriage and wagon superintendent, Taff Vale Railway.

America. — Mr. C. Peter Clark, second vice-president and general manager, Buffalo & Susquehanna Railroad.

Other countries. — Mr. L. Greppi, divisional superintendent (central department for rolling stock and locomotives) of the Italian State Railway.

REPORT N° 1

(America)

By C. Peter CLARK,

VICE PRESIDENT AND GENERAL MANAGER, BUFFALO & SUSQUEHANNA RAILWAY.

The subject of motor vehicles holds a prominent place in the consideration of steam railroad officials, because of the changing conditions tending to constantly lose to competing electric lines, business which was formerly done by them.

The great increase in travel by automobile has had a marked effect in encouraging the feeling in travelers that they should be transported whenever ready to make a trip, rather than when a train is scheduled to run, as was formerly accepted as a matter of course.

The comparatively frequent service of electric roads with the light expense per car mile, can be justified by a number of passengers altogether too small to nearly pay the expense necessary to run a standard steam passenger train.

To meet these conditions railroads having established roadbeds and stations, are naturally anxious to protect their investment by retaining as large a percentage of their passenger travel as possible, and to that end are greatly interested in any apparatus promising service at a cost permitting sufficient frequency and speed to hold the business against their competitors.

Interest in the subject has increased as competition has developed or been threatened, and many attempts have been made to produce suitable equipment for this purpose.

Considerable sums have been spent by some large interests without producing cars susceptible of a perfectly satisfactory trial trip, to say nothing of usefulness thereafter and it seems clearly unjustifiable to ask attention to apparatus which has

*

not received a substantial approval, unless so recently developed that necessary time has not elapsed for pratical demonstration, excepting when special features are incorporated suggesting ideas that may be useful in future developments.

As the most successful builders are those who study the weak points of their vehicles for the purpose of improving them as use indicates possibilities, it is not difficult to see that in small details the car built at the time of writing will be improved, if only in minor particulars, by the time the Congress convenes, so that enumeration of the small matters of detail would serve no good purpose, while general descriptions will indicate the various types, the very latest details and developments which can always be readily obtained by those particularly interested.

Those small and light cars which have not sufficient size to afford space for the transportation of baggage and frequently better suited for inspection than revenue service, are purposely omitted as outside of the intended scope of the subject.

The last published report of the Interstate Commerce Commission of the United States shows passengers carried one mile for the year ending 30 June 1907 as 27,718,554,030, while the number of passenger train miles run in the same period is given as 509,328,042; this gives the average passengers carried per train mile as 54. When the enormous loading of suburban trains running in the neighborhood of larger cities, as well as the heavy trunk lines trains, are taken into consideration, it is painfully evident that a great mileage is maintained at a serious loss, as all the passengers carried occupy but a small part of one car, while the number of employes and weight necessarily moved, involve a considerable expense.

In many of these cases such as branch lines, the connection with main line trains must be maintained though frequency of service offers no increase, making the problem one of economy in operation.

The successful motor vehicle adapted to steam railroad use should be designed to attract business where it is susceptible of development and operate at low cost to reduce the loss where increased frequency of service will not add to the revenue.

Perhaps the most serious opposition which has so far been discovered by those working upon this subject, is found in the attitude of labor towards a device designed to reduce the number of employes per unit below that formerly required for the steam train.

One of the largest interests in the country has been so embarrassed by the labor legislation introduced both in Congress and some of the state Legislatures, specifying that any train, no matter how short, shall carry a crew of at least five men, that they have decided to await the outcome of the agitation before investing further time or money for the development of apparatus which may be deprived of its usefulness through this short-sided policy.

Apparently the fact that a change in apparatus increasing the number of moving units many fold necessarily requires a total increase in the number of men employed is to be prejudiced because the single unit does not require and cannot, with its small load, afford to pay the wages justified by a steam train with many cars.

As a matter of safety, it seems strange that interurban high speed, heavy electric cars can be run up and down hill in the country highways by two men without question, while the operation of a steam motor car upon the branch line of a standard steam road owning its own right of way and without other train upon the branch, should require five men or be rated as such a dangerous operation as to interest investigation by state railroad commissioners.

The speed freely permitted touring cars in public streets to-day would, a few years ago, have seemed proper only for fire engines or ambulances, and it is to be hoped that as the public become accustomed to seeing a boy of fifteen years handle a heavy automobile in crowded streets, that they will becomereconciled to the thought that two men are sufficient to protect passengers upon motor cars, enjoying exclusively the fenced right of way of a railroad company.

The absurdity of a city government restricting steam trains to a speed of six miles an hour where crossing highways at grade in the suburbs, while authorizing touring cars to run up and down the length of the city streets at ten miles an hour, certainly cannot last and with the inevitable public education, should come a popular support for an honest attempt upon the part of the railroads to give the traveling public a frequent service at a low cost.

Previous experiments have shown that cars should be neither too light nor too heavy. The light car has proved of insufficient power to meet the speed expected and those having too much weight upon the heavy end, that of the motor truck, have shown a tendency to destroy the gauge upon the track of branch lines, which are frequently maintained at a cost per mile considerably below that of the main line.

The various types will be discussed by classes.

A. — Those driven by steam.

B. — Those driven by internal combustion engines with a mechanical transmission of power.

C. — Those utilizing internal combustion engines operating generators in connection with an electric drive, with or without accumulators as incidental equipment.

A. — Motor cars driven by steam. — Fuel coal.

Rock Island No. 2551.

Continuing the earliest experiments along the line of steam motor cars, using coal as a fuel, there has recently been exhibited a car built for the Rock Island Company.

It is an improvement of the Ganz Car which was developed some ten years ago in connection with a boiler generating about 80 horse-power and which proved inadequate for the service required by American railroads.

A modification has been adopted by which additional boiler space is secured until the car now claims a capacity of 250 horse-power, with a maximum speed of 50 miles an hour on level track.

The total weight of the car is approximately 100,000 pounds.

The boiler arrangement adopted consists of a horizontal boiler located immediately above the forward bolster with flues at right angles to the length of the car.

By opening two doors which are located between the side door to the motor compartment and that to the baggage compartment (see fig. 1) the end of the boiler is disclosed and by opening the head, the flue sheet is exposed and flues can be easily cleaned from a platform placed beside the track outside the car.

The engine consists of two simple cylinders, entirely enclosed and is mounted in the front truck, connected to cranks upon the rear axle.

The connecting rods and other working parts are contained within cast steel casings which surround the driving axle and cranks and contains oil to insure continuous and automatic lubrication of all working parts.

The valves are of piston type and cylinders 12 × 12 inches. The valve motion is of the modified Hackworth type and all wheels are 36 inches in diameter.

The boiler contains 294 tubes of 1 $^3/_4$ inches about 5 feet long. Total boiler heating surface 700 square feet, with an additional 125 square feet in the superheater of the fire tube type, placed circumferentially around the upper half of the front portion of the boiler. The boiler carries 160 pounds pressure per square inch.

The grate area is 14 square feet and suitable for either hard or soft coal.

Sufficient fuel for 100 miles is carried in a bunker at the front end, and water tanks with a capacity of 1,000 gallons (a supply for 50 miles) are placed beneath the car.

The engineer's compartment is equipped with all necessary valves and control mechanism including air pump, pneumatic sander, pneumatic bell ringer, etc.

Immediately behind the engineer's compartment which contains the boiler, is a small baggage room, about 7 feet long, behind which is a smoking-compartment seating eight, with seats for 40 in the body of the car.

The car illustrated in figure 1 was built for the Rock Island Company with an all steel body which is upholstered in rattan, lighted by acetylene, contains a toilet and has a vestibuled entrance at the rear opening from both sides.

This improved car with 250 horse-power boiler has not yet seen sufficient service to furnish any data as to the cost of operation.

This car was built from designs of the Railway Auto Car Company of New York City by the Baldwin Locomotive Works of Philadelphia.

Motor cars driven by steam. — Fuel oil.

Rock Island No. 2552.

In motor cars where weight is so undesirable and the labor of carrying and handling bulky fuel so objectionable, oil as a fuel offers an attractive study, which was developed by the American Locomotive Company for motor car number 2552 of the Rock Island System.

As seen in figure 2, the car in general appearance and arrangement is much like the one previously described, although, as will be seen from the cut next following, the 250 horse-power engine is of an entirely different design, being in brief a small locomotive with a single pair of 38 inches drivers, operated by the Walschaerts valve gear.

The car is 56 feet long and weighs 100,000 pounds of which, 61,700 pounds is on the motor truck (see fig. 3) with a trifle over half upon the driving wheels. This car has attained a speed of 60 miles an hour and as oil is used for fuel, the labor required of the engineer is much reduced.

The car body is entirely of steel except the interior finish, and is built in the interest of lightness with truss rods to assist in reducing vibration to be expected from the tanks carrying 1,000 gallons of water and 100 gallons of oil.

The boiler is of the horizontal return tube type, the fire and smoke box both being on the front end, the gases of combustion passing from the fire box through the lower half of tubes to an intermediate smoke chamber at the back and thence forward through the upper tubes to the smoke box and stack.

The barrel of the boiler is 61 $^1/_8$ inches long and 49 inches in diameter at the fire-box and and 44 inches in diameter at the rear.

The boiler contains 428 tubes of 1 $^1/_4$ inches in diameter about 3 feet and 10 inches long. The heating surface of boiler is 566 square feet, superheater 38 square feet, total 624 square feet.

The superheater is located in the intermediate smoke box chamber upon the rear where the temperature of the gases is high. Each of the 16 superheater tubes bent into loop are connected with the front or saturated steam compartment on one end, and the superheated steam compartment at the other.

The interior of the fire-box is lined with brick for burning oil which is introduced through a burner of special design in the fire door (see fig. 4).

The engine is of the two-cylinder cross compound type, cylinders 9 $^1/_4$ inches and 14 $^1/_2 \times$ 12 inches. The Mellin system of compounding being employed. The springs of the driving truck are arranged to give three point suspension.

The car may be lighted by oil, Pintsch gas or acetylene as desired.

B. — Motors cars driven by internal combustion engines with a mechanical transmission of power.

McKeen Motor Car.

With the development and simplification of the internal combustion engine, producing in small space power both efficient and reliable, as illustrated by the now infrequent failures of the first class automobiles, naturally comes the thought of application to the motor car.

Instantly ready, clean, tireless and compact, it promises many extremely desirable features.

In 1904, the Union Pacific decided to experiment towards the development of a car using gasolene, which should meet the recognized requirements of a successful motor car.

Since the completion of the first car in 1905, the same interests have continued experimenting, improving and building motor cars of this description, but the demand for the car soon required more space and attention than could be given in the regular shops of the Union Pacific and the superintendent of motive power of that company, Mr. W. R. McKeen, resigned from the service of the Union Pacific and organized a company with works at Omaha, Nebraska for the exclusive building of equipment of this class.

Although several different types have been built in the last four years, they have simply shown the evolution of the original idea.

The first car was 31 feet in length, mounted upon one four wheel truck.

The cars now being built (see fig. 5) are 70 feet in length with compartments for engine, baggage, railway post office, if desired, smoking compartment and passengers.

With the pointed front, the wind resistance is appreciably reduced and the consumption of gasolene correspondingly lowered.

The shops fitted for the building of these cars have been provided with special machinery for the purpose of making parts interchangeable and by the most improved methods, so that by the use of the best material, failures and breakage upon the road shall be minimized.

The fact that the entire works are given over to the manufacture of these cars has produced, in four years, improvements which could not have been expected in a much longer time, had the building of an occasional car been an incident in shops maintained for other classes of work.

The interior partitions are, of course, dependent upon the requirements of the service and locality. It is quite generally considered necessary to provide facilities for handling baggage with the passengers, so that practically all cars are equipped with baggage room, unless the amount of baggage and express justifies the hauling of a trailer, when the car itself can, of course be devoted exclusively to the seating of passengers.

Fig. 1. — Rock Island steam motor car No. 2551.

Fig. 2. — Rock Island motor car No. 2552.

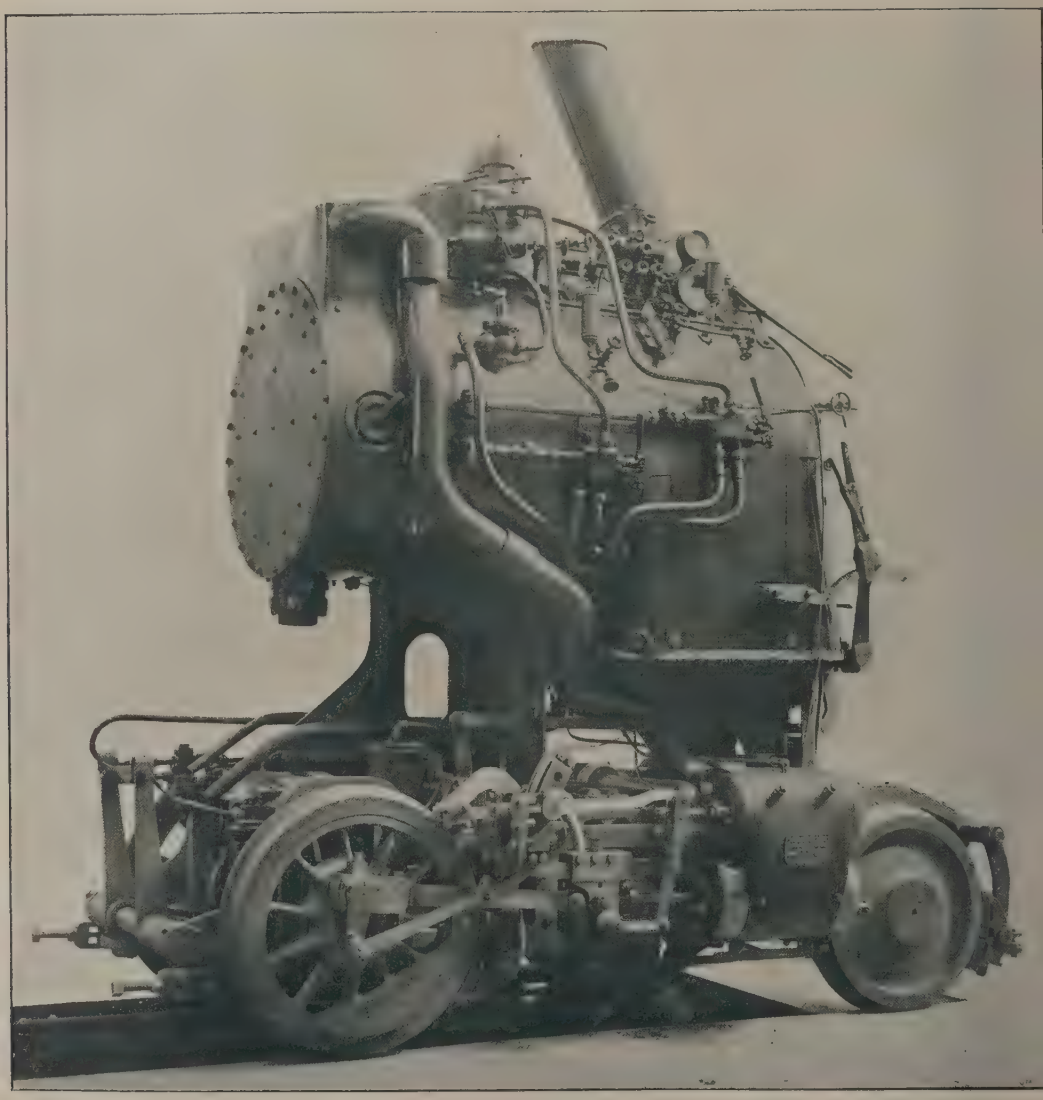

Fig. 3. — View of boiler and engine, Rock Island No. 2552.

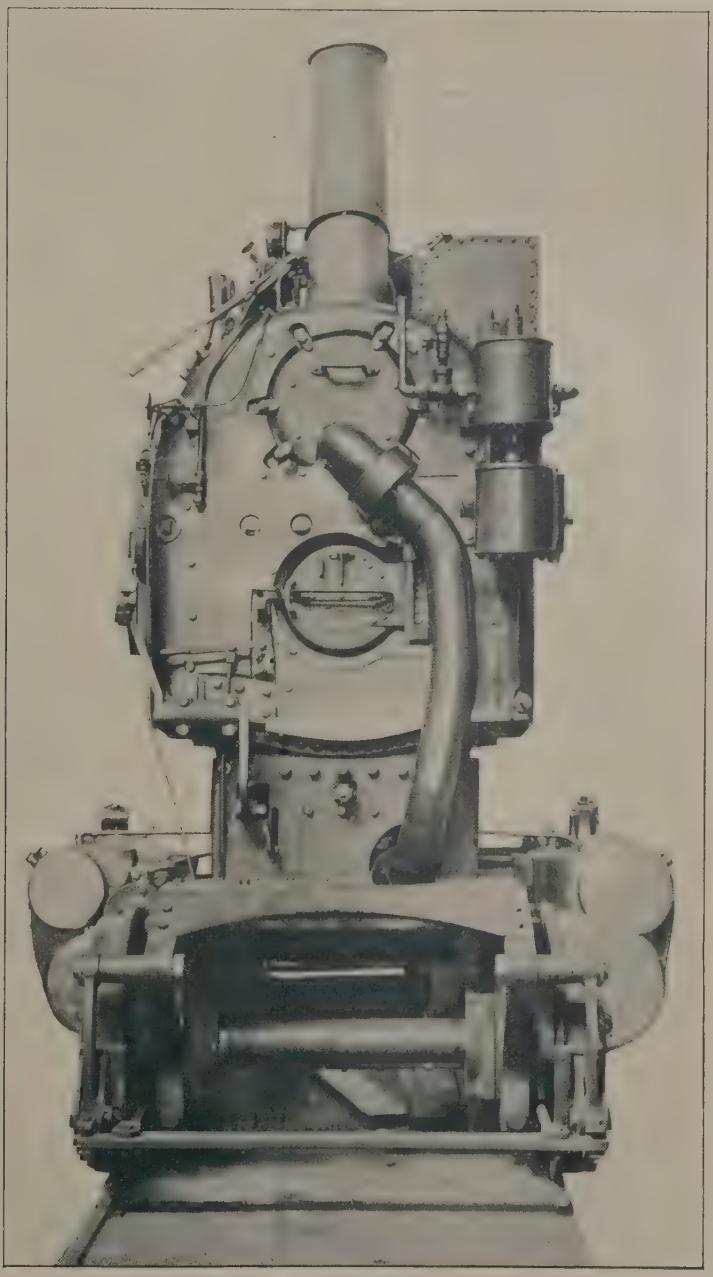

Fig. 4. — View of boiler and engine, Rock Island No. 2552.

Fig. 5. — McKeen motor car.

If an entire 70-foot car is furnished with seats, it may carry as many as 105 persons, practically double the average train load of the United States and with the 200 horse-power engine on any reasonable grade, no difficulty is found in handling a trailer at satisfactory speed.

What appears as the accepted arrangement for motor cars is followed, the engineer and engine, occupying the front of the car, which is carried upon a four wheel truck as shown in figure 6.

The six vertical cylinders are placed over the center of the truck and drive a shaft located between and parallel to the axles of the front truck.

Connection between the engine axle and the axle carrying the driving wheels is made by a five-inch silent-running chain, plainly seen beside the friction clutch on center of front axle.

Compressed air is used to start the large engine as well as for brakes, elevation of gasolene from tanks below the car to the engine, whistle, etc.

The air is supplied by a small and compact air compressor, which is started easily by hand.

The stored air from the reservoir is admitted to the regular cylinders until the carbureter charges the engine sufficiently to commence explosions.

After the engine is started, the friction clutch working in connection with the counter shaft giving powerful low speed applies the power to start the car, after which the counter shaft is disconnected and speed manipulated by increasing or decreasing the supply of gasolene. This low speed connection is used only in starting and moving the car about its length. There are no gears in service except during this brief period.

The six cylinders of the standard engine rated as 200 horsepower, are 10 inches in diameter with 12 inch stroke.

The cylinders have water jackets cored in the casting, the water being cooled by radiators under the car in hot weather and as much as may be desired, used for heating the car in cold weather.

One of the cars in switching service handled a 40-ton car of coal weighing 111,300 pounds, gross, upon a trestle up an 8 per cent. grade, while upon level track, speed up to 79 miles an hour has been made.

The weight of this 70-foot car in working order, is 68,000, about 42,000 pounds of which is upon the front truck and approximately 25,000 pounds upon the 42 inch drivers, which are the lead wheels of the front truck.

The weight of the 55-foot car is 60,000 pounds.

Light is either by acetylene from special designed generator, or commercial stored acetylene.

These cars on long runs fully equal, and frequently exceed the speed of express trains, and the distance covered between terminals is materially in excess of locomotive practice.

There were, in June 1909, forty-six cars in service in different parts of the country,

between the Valley of the Hudson River and the Pacific Coast. Fourteen additional cars built on order are substantially completed and ready for service at the present time, making a total of 60. Material is also being assembled and work commenced on 20 additional orders.

The efficiency figures furnished by the Union Pacific Railroad which have had a number of the cars in use for several years, including some of the earlier ones, report but 61 failures out of 9,883 motor car trips, most of which were due to breaking in of inexperienced men, although the car appears to be easily understood by a man of ordinary mechanical intelligence. One car, No. 19 upon the Union Pacific Railroad completed an even year's daily service, hauling regularly a trailer and had but two failures of the engine, during that time.

C. — Motor cars utilizing internal combustion engines operating generators in connection with an electric drive, with or without accumulators as incidental equipment.

General Electric Company's Car (fig. 7).

The evident demand for satisfactory motor cars shown by the interest taken in all developments announced through the railroad journals, have enlisted the attention of the General Electric Company, representing the same general interests as the Thomson Houston Company abroad.

They believe that the production of steam as a source of power is unnecessary and have adopted an 8-cylinder, 4 cycle gasolene engine of 125 horse-power at 550 revolutions per minute direct connected to an 8 pole 80 kilowatts 600 volts commutating pole generator and direct coupled with $3\ ^1/_2$ kilowatts 32 volts exciter (see fig. 8).

The cylinders are 8×8 inches with water jackets cored in close grained grey castings and are cooled by thermo siphon circulation, having radiation of 2,000 square feet surface located on roof of car.

The bearings throughout consist of bronze cages lined with babbitt. All valves are of nickel steel.

Automatic force feed lubrication is applied to all wearing surfaces.

Ignition is by high tension magneto and plugs, gasolene being supplied by a plunger pump directly driven by the engine.

The gasolene is carried in a steel tank holding ninety gallons, located below the car floor and is filled from the outside.

Power is applied to both pairs of wheels of the forward truck through two 600-volts 100 horse-power railway motors.

A special controller is furnished by which the motors are placed progressively in series and parallel, and the voltage applied to them controlled by varying the strength of the generator field.

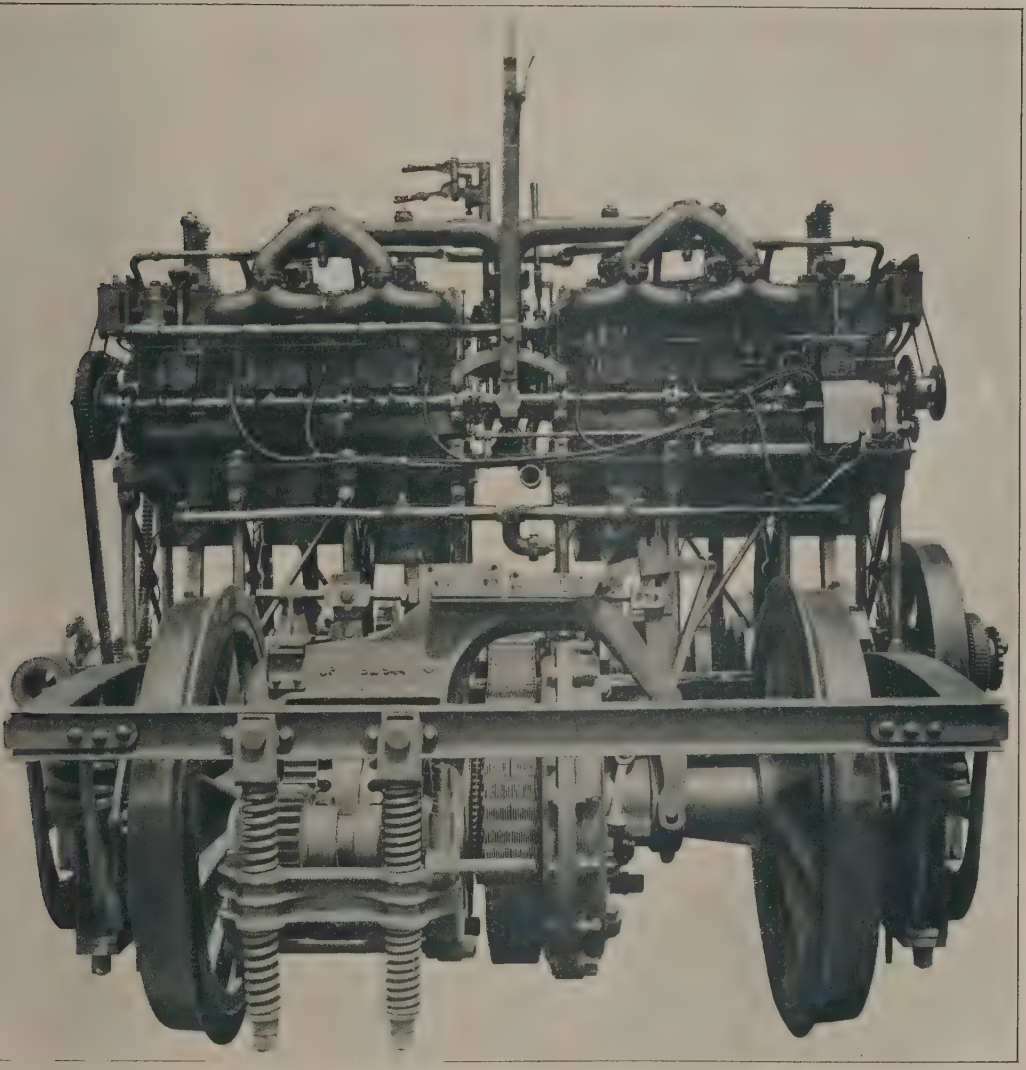

Fig. 6. — McKeen motor truck. — Front end.

Fig. 7. — General electric Company car.

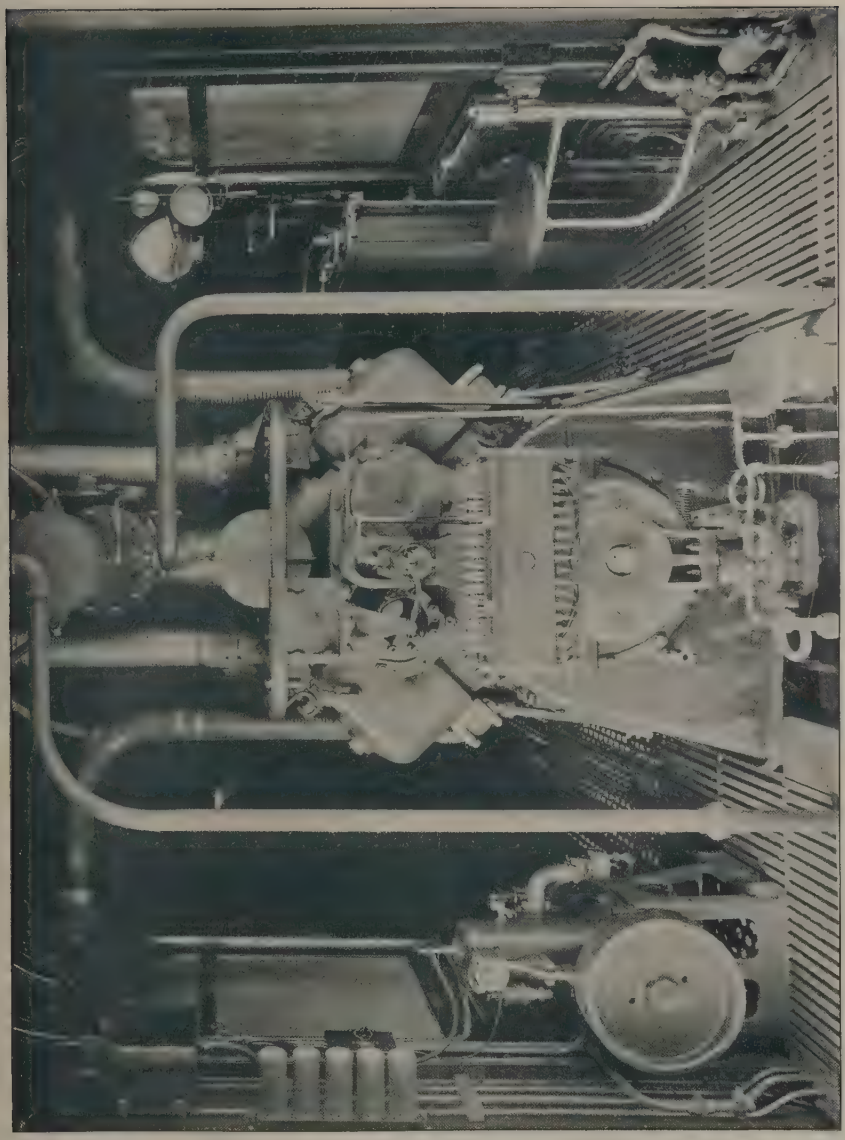

Fig. 8. — Interior of cab. — General electric car.

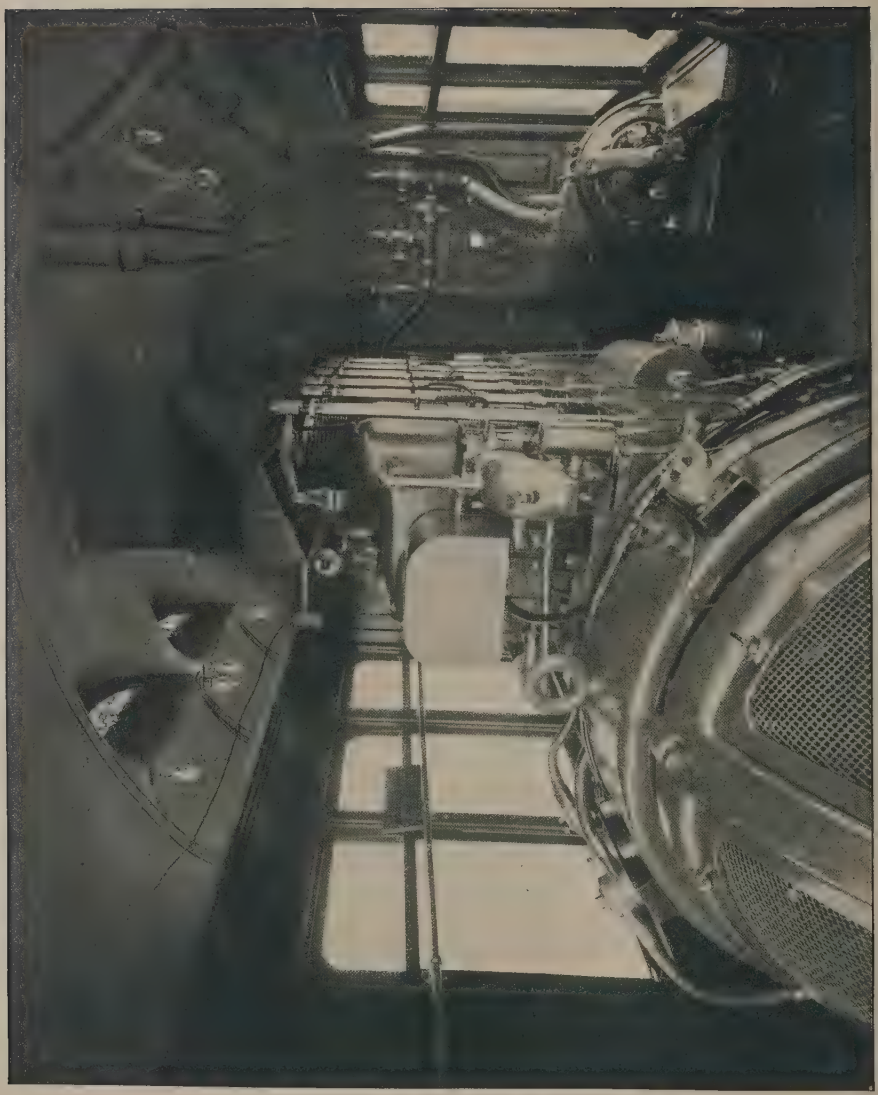

Fig. 10. — Car Irene. — Interior of engine compartment from the front end.

If desired, the car can be furnished with trolley for city work, using the same motors.

The car is finished with the usual equipment for controlling the air brakes, electric lights, whistle, gong, etc.

Compressed air is used to start the main engine through admission to the main cylinders and is regularly furnished by a small 4 × 4 inch single cylinder pump driven from the main crank shaft. If the car stands long enough to lose its supply of stored air, it can be charged by a small independent pump.

The car can be started, stopped and reversed without stopping the engine, and by a simple arrangement of the circuits, the power furnished the motors is under such control that the greatest flexibility is obtained, such as might be obtained with an unlimited number of gears but without the objectionable jar frequently occuring when gears are changed.

The car is electrically lighted by 25-volt incandescent lamps taking power from the exciter when car is running, and from storage battery below the floor when engine is shut down.

Car is heated by hot water circulation utilizing the exhaust gases.

The weight of the car exhibited at Atlantic City in June 1909 which measures 50 feet over all with steel body is given as 70,000 pounds, of which about 45,000 is on the motor truck.

Strang gas-electric car.

A different arrangement of the gasolene engine for electric production and application using accumulators is shown in the Strang Gas-Electric Car Irene (fig. 9).

As a substitute for the mechanical transmission of power direct to the drivers, the Strang Gas-Electric Car Company of 15, Wall Street, New York, have built four cars each of which is furnished with a generator of about 150 horse-power at 425 revolutions per minute, furnishing electric power.

A vertical 4-cycle type engine with 6 cylinders, 10 1/2 × 9 inches in connection with a generator of 85 kilowatts furnish direct current at 250 volts.

The power is applied to both axles of the front truck by 100 horse-power motors. When not in motion, any surplus current generated is stored in a battery of 112 cells, having a capacity of 300 ampere hours.

High grade material has been utilized and all the main working parts are located in the crank case which is completely enclosed to retain oil and exclude dirt. The various bearings are oiled by means of a rotary gear pump. Ignition is of the high tension type.

The cylinders are jacketed for water circulation connecting with radiators upon the roof which is designed so as to conceal them. The circulation is secured by a turbine pump driven by independent 2 horse-power motor, shown at right.

A view of the engine located in the front compartment, which is 14 feet long gives a general idea of the mechanical arrangement (fig. 10).

The passenger compartment is heated in cold weather by the circulation of hot water from the cylinder jackets and lighted by electricity.

In addition to three located upon an interurban line in Kansas, the Company has demonstrated its system by the car Irene herein illustrated.

The Irene measures 62 feet over the bunters. The car body is built of steel finished handsomely with vermillion wood, inlaid.

The weight of the car is 114,000 pounds and has a seating capacity of 41 passengers, one half of which are given individual chairs which increase comfort, although decreasing capacity.

In starting the car or negotiating heavy grades, the electricity in storage battery is available to supplement the work of the engine through the generator and thus carries the "peak" furnishing results which would otherwise require a larger and heavier engine and generator.

While this car has traveled a great many thousand miles for exhibition and given tests upon different roads, it has not been in continuous service in any one place long enough to determine the actual cost of repairs and renewals of such features as the storage battery.

The car upon the Pennsylvania Railroad tracks is said to have made a mile in 57 seconds, with about the same speed under general service conditions as an ordinary steam train.

SUMMARY AND CONCLUSIONS.

The fact that interest in this subject continues on every side and that different roads and Companies continue to produce new types of apparatus upon the same general line is a very encouraging sign.

The question of expense, first cost of repairs and depreciation cannot be satisfactorily determined by the performance of isolated cars under different weather and topographical conditions where the prices for the same kind of fuel and service vary greatly.

The marked tendency of the past three of four years based upon the numbers built, is unquestionably in favor of the car operated by gasolene and without the additional electrical complications, but this, by no means, proves that the experiments of the next three or four years may not introduce new features giving even more satisfactory apparatus at ess cost and susceptible of even cheaper operation.

The amount at stake is so large that the continued study of the subject is clearly warranted, and circumstances appear to justify the belief that apparatus of this kind alone will enable steam railroads to protect passenger business which otherwise will be lost to them.

REPORT N° 2

(all countries except Great Britain and America)

By L. GREPPI,

DIVISIONAL INSPECTOR OF THE ITALIAN STATE RAILWAY.

General considerations.

The list of questions, which is given in appendix I, was addressed to seventy-four railway administrations, forty-three of whom sent us answers.

Twenty-six administrations stated that they had no automotor cars or equivalent small locomotives in use at present, that they had never had any, and that they did not intend to have any built.

The answers we can utilize in discussing the subject, are thus reduced to seventeen, some of which give very detailed information about the different points touched upon in the list of questions, and others only give information about some of them.

Although the information officially collected is of considerable extent, yet it cannot be considered complete, as the answers we have received do not include all the administrations which have motor vehicles in use.

The question considered has lately been the subject of several interesting publications, and we have been able to consult with advantage the information contained, more especially, in the *Handbuch für Triebwagen für Eisenbahnen* by Mr. C. Guillery, State Councillor, of Munich (1), and in *Motorwagen und Lokomotive*, by K. Spitzer, chief engineer, of the Austrian Northern Railway, and Dr. Victor Krakauer, secretary of the Austrian Northern Railway (2).

(1) Published by R. Oldenbourg, Munich and Berlin, 1908.
(2) Published by A. Holder, Vienna, 1907.

The question of automotor cars was also fully discussed at the XV International Congress of tramways and light railways, which met at Munich in September 1908; the very interesting and very complete report of Mr. E. A. Ziffer, civil engineer, president of the Council of administration of the railways of local interest of Bukovinia (1), which is the most recent work on the subject, has been very useful to us, the more so as it contains detailed information not only about services of automotor cars and of small locomotives on secondary railways, but also about applications of this system of operation made by several of the main-line railways. Mr. Ziffer's report retains its full value, the development of the application of automotor cars having made no appreciable progress since its publication.

In order to be as complete as possible, we have, in the report which follows, utilized the information taken from the above works which supplements the answers received to our list of questions.

Moreover, detailed descriptions of the most recent types of automotor cars have appeared in the technical reviews of the last years, which can be usefully consulted by those more especially interested in the details of construction of such cars. The types used may be considered sufficiently well known today in the technical world to relieve us from giving much space to the descriptive part, and to enable us to limit our investigations to points in connexion with the working.

Our list of questions, which is given in appendix I, was drawn up in such a way as to enable us to consider the very different types of automotor cars on the railways of the continent of Europe, specially from the point of view of conditions of operation, without neglecting the trials which have been made to replace automotor cars by small locomotives, particularly by such locomotives especially designed for this purpose.

In our report, we have classed with the automotor cars the motor luggage-vans, which have externally the appearance of an ordinary luggage-van, such as the motor luggage-vans of the Italian State Railway. On the other hand, we have considered as locomotives the motor luggage-vans of the French State Railway, which have the appearance of a true tank locomotive with a large cab which includes a compartment for luggage.

We have not considered the electric cars taking current from outside, for as they are dependent on fixed installations for generating and transmitting the energy they belong to the problem of electric traction, which is outside the scope of our present subject.

The twenty-six administrations which informed us that they have no automotor cars in use or on order are the following :

Alsace-Lorraine State Railway;
Oldenburg State Railway;

(1) Published by the *Union internationale des tramways et des chemins de fer d'intérêt local*, Imprimerie des travaux publics, Brussels, 1908.

Bukovinia Local Railway;
Austrian North Western Railway;
Mohacs-Pecs Railway (Hungary);
Belgian Northern Railway;
Danish State Railway;
Bulgarian State Railway;
Egyptian State Railway;
Andalusian Railway;
Madrid-Caceres and Spanish Western Railway;
Spanish Northern Railway;
French Eastern Railway;
French Midi Railway;
Compagnie générale des chemins de fer et tramways (Paris);
Gafsa Railway (Tunis);
Dutch State Railway;
Portuguese State Railway;
Nicolas Railway (Russia);
Moscow-Kursk-Nijni and Mourom Railway (Russia);
Sizran-Wiazma Railway;
Trans-Caucasus Railway;
Trans-Baical Railway;
Swedish State Railway;
Norsk-Hoved Railway (Norway);
Rhetian Railway (Switzerland).

The seventeen other answers to the list of questions may be subdivided as follows :

The Baden State Railway made trials in 1901 with a Serpollet steam car and an electric accumulator car, now no longer used; at present it does not intend to make any other application.

Three administrations (Teplitz Railway, French Western Railway, Norwegian State Railway) do not use automotor cars, but they state that they have established several local services which are operated with small tank locomotives, *of old type*.

The following thirteen administrations are at present using automotor cars of different types :

Bavarian State Railway;
Saxon State Railway;
Wurtemberg State Railway;
Austrian State Railway;
Austrian Southern Railway;
Belgian State Railway;

Belgian National Suburban Railway Company;
French State Railway;
Paris-Orleans Railway;
Paris-Lyons-Mediterranean Railway;
St. Quentin Departmental Railway;
Swiss Federal Railway;
Italian State Railway.

I. — Type and particulars of the automotor cars used.

The principal data and particulars supplied by the administrations consulted, concerning the different types of automotors cars, and the small locomotives used for similar services, are reproduced in a table in appendix II.

Class of motor. — As we have already stated, thirteen administrations, out of the seventeen which sent us affirmative answers, are at present using automotor cars.

Of these thirteen administrations, ten use steam motors, while three have in succession given up their use; these are the Saxon State Railway, the Swiss Federal Railway, and the Belgian Suburban; the two former had tried Serpollet cars and the latter Rowan cars.

Internal-combustion motors, with mechanical transmission of the motion to the wheels, are utilized by four administrations : the Saxon State, the Swiss Federal, the Wurtemberg State and the Austrian State; these use in current practice both cars with petrol motors as well as cars with steam motors of different types.

These four administrations also use one and the same type of car and of internal-combustion motor : the Daimler petrol motor.

The system of cars having an internal-combustion motor, combined with an electric transmission of the motion, that is to say, with a dynamo driven by the internal-combustion motor, and electric motor fed either direct by the dynamo, or through a battery, is not in current use by any of the administrations which have sent us answers. The Belgian Suburban however informs us that it is just about to try a *mixed system*, in which the cars are equipped with a petrol or lean-gas motor (the gas-producer being carried on the car), dynamo, accumulators and electric motors, designed by the *Compagnie internationale d'électricité de Liége*.

The administration of the Italian State Railway, at the time of the Milan exhibition, made two trial runs with a benzo-electric automotor car on the Weitzer system, belonging to the Arad-Csanàd Railway; this car has two axles, with a 70-horse-power de Dion-Bouton petrol motor; but the system, which appeared to be a little complicated and delicate, has not been applied, in spite of the favourable results of the two trial runs.

Mr. Guillery's book, mentioned above, and Mr. Ziffer's report to the Munich Congress however show that the Weitzer mixed system has been applied rather exten-

sively on the Arad-Csanàd Railway, and that it is being tried on the Hungarian State Railway. A car with petrol motor and electric motor, of a special type, is going to be tried on the Prussian State Railway.

Electric accumulator automotor cars are used by three of the administrations which sent answers to our list of questions : the Bavarian State, the Saxon State and the Belgian State railways. Each of these administrations has but one automotor car of this system in use, so that these applications are rather of the character of mere trials.

The Italian railways, during the period 1900-1904, used accumulator cars of two types, one for the local service on the Milan-Monza line, the other for the whole passenger service on the Bologna-San Felice-Poggio Rusco line. These automotor cars were then withdrawn from the service and transformed into ordinary carriages, owing to the cost of upkeep of the first of the two types, and to the unforeseen development of the traffic in the case of the second type.

We believe that the Wurtemberg railways also formerly used accumulator automotor cars.

Among the administrations which sent no answers to our list of questions, but which are at present using accumulator automotor cars, we may mention the Prussian State Railway, which uses a considerable number (see Messrs. Guillery and Ziffer, *op. cit.*).

As regards the total number of units *actually* used on the railways from which we have received answers, we find :

185 automotor cars with steam motor;
7 automotor cars with internal-combustion motor;
3 electric accumulator automotor.

To these figures, we must add the benzo-electric automotor cars, and cars of other similar mixed systems, which are being tried in Belgium and are being used on railways which have sent no answers to the list of questions, as well as the Prussian State accumulator cars, which we have mentioned above.

It follows from what we have stated, that from the point of view of the qualities specially required for automotor cars, and the services for which they are used, there is at present a tendency to extend investigations and experiments on the subject of cars with petrol motors or benzo-electric motors, or with accumulators; it seems, however, that a solution which is entirely satisfactory for current applications has not yet been obtained, and consequently steam automotor cars are still the most used in spite of the almost inevitable disadvantages inherent in the different types of this system.

Number and arrangement of the axles. — The automotor cars at present in use have two, three or four axles.

Limiting ourselves to the data supplied by the administrations which sent answers to our questions, we find that the following are at present in use :

—	With steam motor.	With petrol motor.	With accumulators.
Automotor cars with 2 axles	34	7	1
— 3 —	122	...	...
— — 4 —	29	...	2

The use of two axles when internal-combustion motors are used, is explained by the generally limited power of motors of this system used at present in Europe on automotor cars.

In the case of steam automotor cars, there is an evident tendency to prefer cars with three or four axles, in order to make it possible to get a motor sufficiently powerful to have the necessary flexibility in the service and also to make it possible to increase the capacity of the car. The same consideration applies to electric accumulator cars.

In the case of the two-axle automotor cars, the wheelbase varies between 4 and 6·320 metres (13 ft. 2 in. and 20 ft. 9 in.); in the case of the larger wheelbases, radial axle-boxes are used, to facilitate running round curves. All these cars have one driving axle only; the second is simply a carrying axle, except in the case of the Bavarian two-axle accumulator car, where the two axles are independent, but are both driving axles.

The three-axle cars are most numerous; they are of five types, which as regards the arrangement of their axles, may be classified as follows :

a) The old Belpaire cars of the Belgian State Railway, first pattern, and the motor luggage-vans of the Italian State Railway, series 60 (classed in the present report with the automotor cars, as stated above); these have a shorter wheelbase which is quite rigid, of 4·100 and 4·600 metres (13 ft. 5 $^{7}/_{16}$ in. and 15 ft. 1 in.) respectively (see fig. 1). The driving axle is in the middle and coupled to the leading axle; the trailing axle is only a carrying axle;

b) The Purrey car of the Orleans Railway, series AV 1, with a wheelbase of 8·200 metres (26 ft. 10 $^{7}/_{8}$ in.). The driving axle is in the middle; the two others are simply carrying axles and are fitted with axle-boxes with side play for running round curves;

c) The Purrey car of the Orleans Railway, series AV 2-11, and that of the Paris-Lyons-Mediterranean, series VACE/21-32 (fig. 2), which consist of two parts :

1° A motor truck with two axles; its frame, which is separate from that of the car, carries the boiler and motor, as well as the water and fuel supply;

2° A carriage body, with one end supported on the motor truck and the other on a trailing axle. The wheelbase of the motor truck is 3·200 metres (10 ft. 6 in.); only the second axle is a driving axle. The total wheelbases of the cars are 11·400 and 12·400 metres (37 ft. 5 in. and 40 ft. 8 in.), for the cars of the two railways respectively; the distances from the centre of the truck to the trailing axle are 9·500 and 10·500 metres (31 ft. 2 in. and 34 ft. 5 in.) respectively.

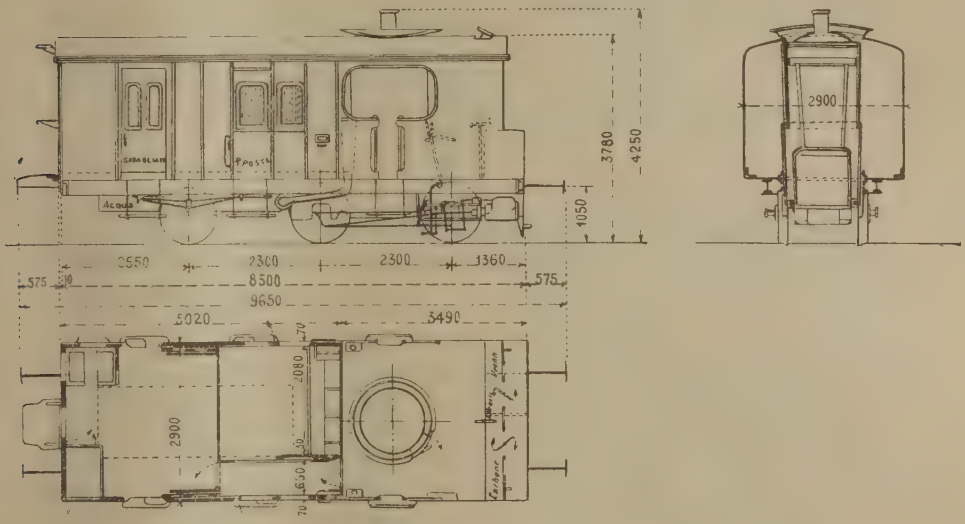

Fig. 1. — Italian State Railway. — Motor luggage-van, series 60.

The four-axle automotor cars have varying wheelbases; the maximum is 16·240 metres (53 ft. 3 3/8 in.) (cars series 86 of the Italian State Railway).

Among the four-axle steam cars, the old Belpaire cars of the Belgian State Railway, second pattern, alone have the four axles mounted on one and the same frame, which is also that of the car. The two leading axles are coupled, the third and fourth are carrying axles; the latter has radial axle-boxes. The rigid wheelbase is 4·600 metres (15 ft. 1 in.) and the total wheelbase is 9·660 metres (31 ft. 8 in.)

The other four-axle steam automotor cars, which are of five types, all consist of two separate parts, similar to the three-axle cars with independent motor truck, of the Purrey type mentioned above. The frame of the motor truck carries the boiler and the engine, thus forming really a separate machine. The body of the car is supported on the motor truck at one end and on a carrying trailing bogie at the other. The two axles of the motor truck are coupled on the automotor cars of the Bavarian State Railway, series MCCi (fig. 3) and on those of the Italian State

Railway, series 86 (fig. 4). On the other hand there is only one driving axle on the DWss automotor car of the Wurtemberg State Railway and on the cars, series 85, of the Italian State Railway (fig. 5). No information is given on this subject as regards the four-axle cars of the St. Quentin Departmental Railway.

These latter cars, as well as the four-axle, series DWss cars of the Wurtemberg State Railway, are narrow gauge (see appendix II). All the others considered in this report are standard gauge.

As regards the two types of four-axle accumulator cars, that of the Belgian State is on two bogies, as usual, and two of the axles are driving axles; that of the Saxon State consists of two half-cars each with two axles, which are permanently connected by an articulated junction; the frames of the two half-cars bear on the axles direct.

Weight of the automotor cars. — The weight of the two-axle steam automotor cars, empty, varies between a minimum of 13 tons (12·8 English tons) (car of the Ganz type, with de Dion motor and boiler, of the Bavarian State Railway) and a maximum of 21·4 tons (21·1 English tons) (Komareck car, 1001, of the Austrian State Railway).

In the case of the three-axle steam cars, the minimum is 19·8 tons (19·5 English tons) (Belpaire car, first pattern of the Belgian State Railway) and the maximum is 29·8 tons (29·3 English tons) (Purrey car, Paris-Lyons-Mediterranean Railway).

The weight of the four-axle steam cars (excluding the narrow-gauge types of the Wurtemberg State and of the St. Quentin Departmental Railways, and the old Belpaire cars, second pattern, of the Belgian State Railway, which weigh only 24·1 tons [23·7 English tons]) varies between 38·5 tons (37·9 English tons) (cars, series 85, of the Italian State Railway) and 43 tons (42·3 English tons) (cars, series MCCi, of the Bavarian State Railway).

The corresponding limits of the weights in working order, but without passengers, luggage or mails, are as follows :

Cars with 2 axles	14·4 to 24·2 tons	(14·2 to 23·8 English tons).
— — 3 —	23·6 to 32·8 —	(23·2 to 32·3 —) (1).
— — 4 —	42·5 to 48·0 —	(41·8 to 47·2 —).

The petrol cars, which as stated above are all Daimler cars, with two axles, weigh empty between 13·1 and 16·3 tons (12·9 to 16·0 English tons); the petrol supply does not increase the weight by more than 200 kilograms (440 lb.) as a maximum.

The two-axle accumulator car of the Bavarian State Railway weighs 26·8 tons (26·4 English tons); the four-axle one of the Saxon State Railway weighs 44·4 tons (43·7 English tons).

---

(1) This maximum refers to the motor luggage-vans series 60 of the Italian State Railway.

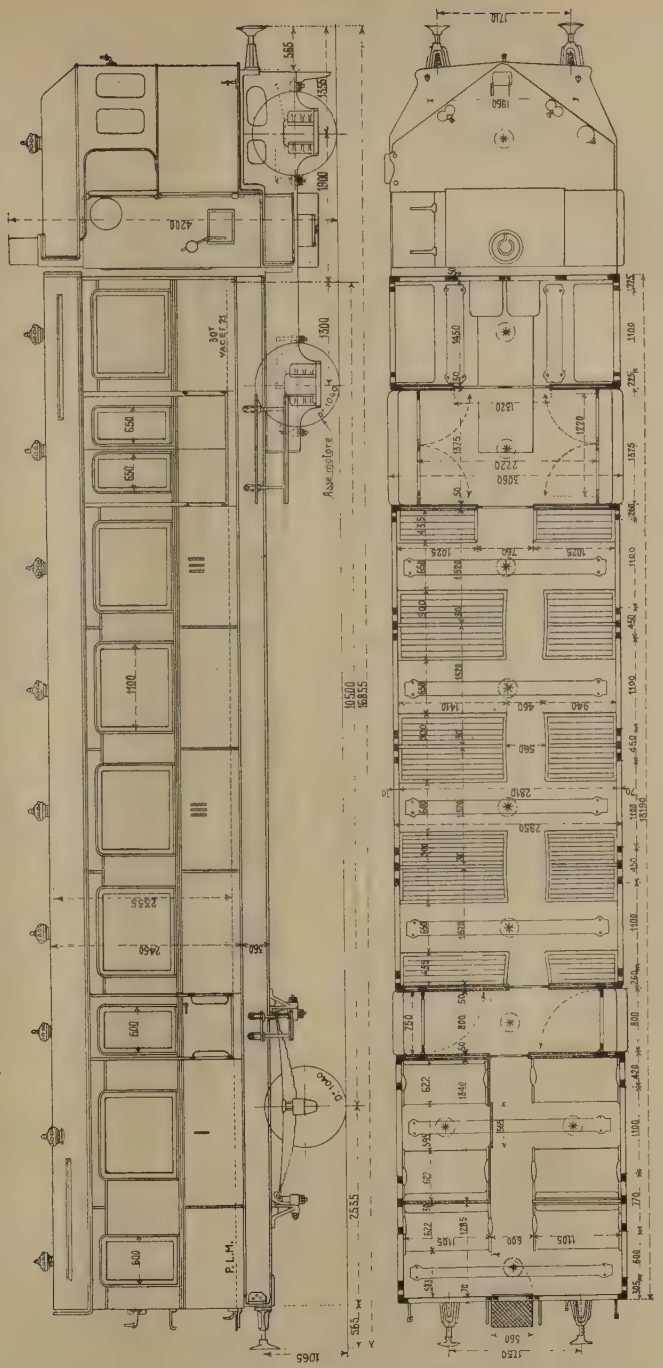

Fig. 2. — Paris-Lyons-Mediterranean Railway. — Purrey steam car.
Explanation of Italian terms : Asse motore = Driving axle.

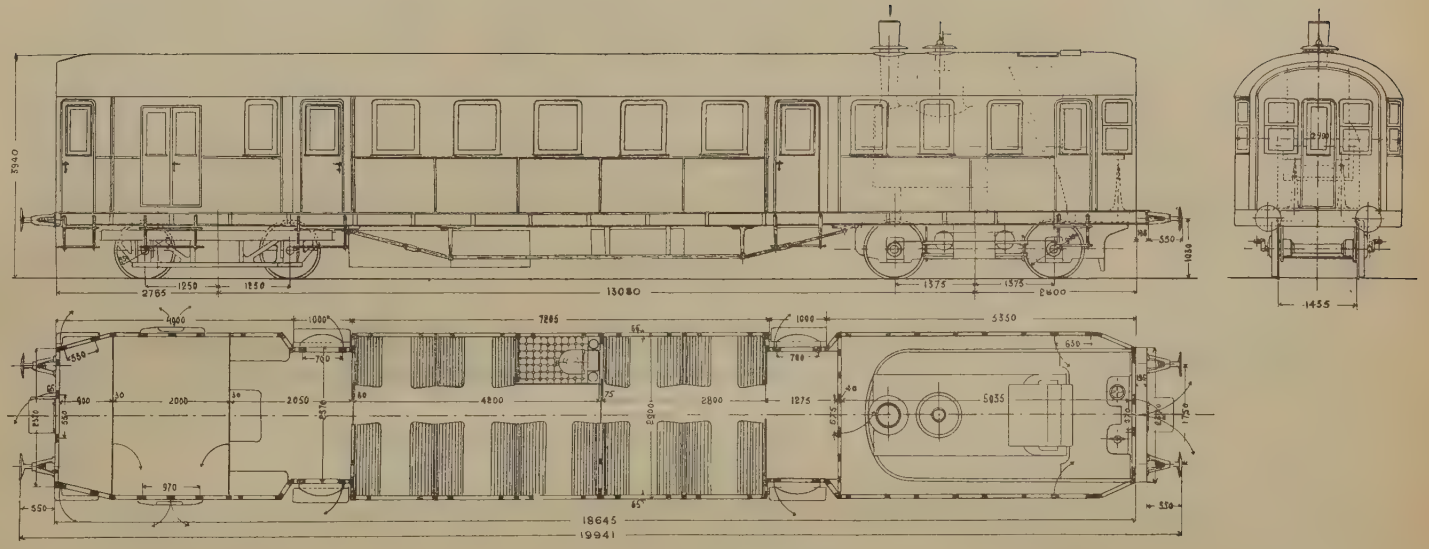

Fig. 3. — Bavarian State Railway.
Steam car with locomotive type boiler and Maffei engine. Series MCCi.

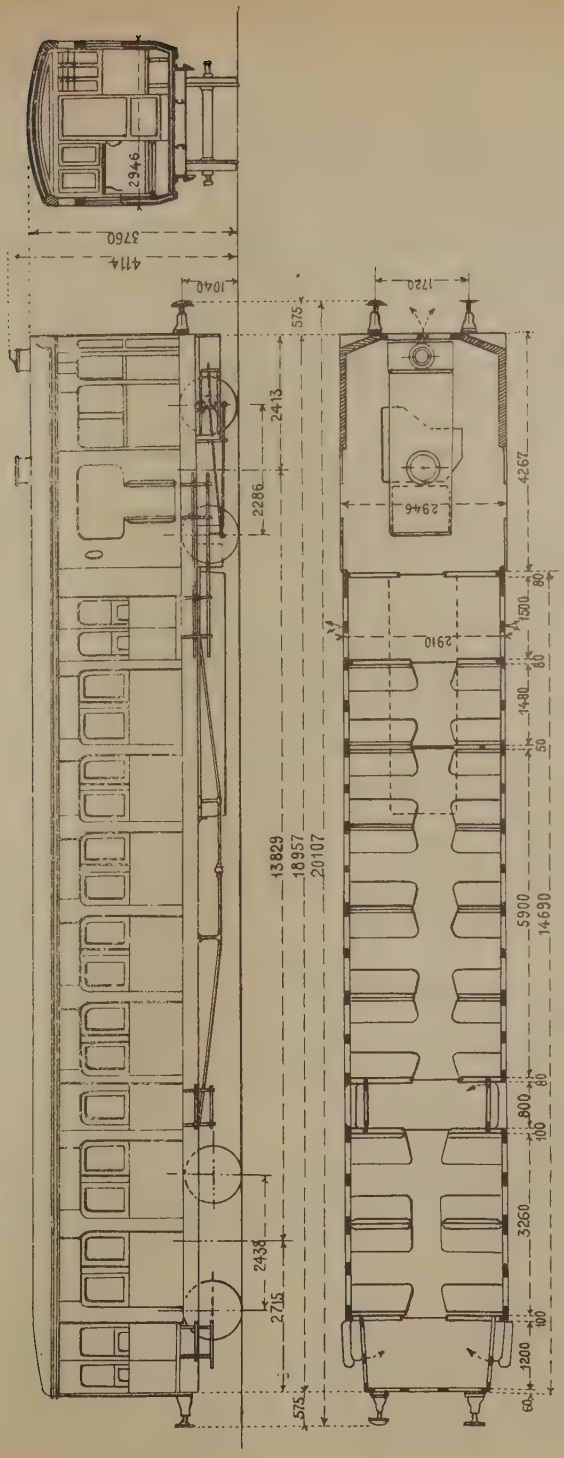

Fig. 4. — Italian State Railway. — Kerr-Stuart steam car with longitudinal boiler. Series 86.

The total service weights, including passengers and luggage, of the automotor cars of the different types are given in the table in appendix II. The lightest cars are those with petrol motors; the heaviest are the four-axle steam cars of the Bavarian State Railway.

The maximum axle-load, excluding the petrol cars and the old Belpaire cars of the Belgian State Railway, reaches or exceeds about 11 tons (10·8 English tons) in all the cars that we are considering.

The lower limit is found in the cars of the Ganz type, with de Dion boiler and motor. The Serpollet, Purrey, Kittel and Komareck cars have maximum axle-loads which vary between 12 and 14·5 tons (11·8 and 14·3 English tons). The motor luggage-vans, series 60, of the Italian State Railway, have a load of 12·5 tons (12·3 English tons) on the driving axle. The highest values are shown by the large steam cars of the Bavarian State Railway (series MCCi) and of the Italian State Railway (series 85 and 86) with two bogies; the loads on the driving axles of these cars are 15·5, 15 and 15·8 tons (15·3, 14·8 and 15·6 English tons) respectively.

Number of classes and of seats for passengers, load-limit. — As regards the number of classes, the one hundred and ten (1) passenger cars belonging to the administrations which sent answers to our list of questions are classified as follows :

a) Forty-five cars, representing eleven different series, have one class only, generally the third. On the cars of the Wurtemberg State Railway, the one class is called the fourth class. Only in the case of a car of the Purrey type, belonging to the Orleans Railway, is the one class the first class; this car is intended always to haul ordinary third-class carriages;

b) Sixty-two cars, representing seventeen series, have two classes (first and third, or second and third);

c) Three narrow-gauge cars, with four axles, of the St. Quentin Railway, have three classes.

On most of the automotor cars, a certain amount of standing room is provided, generally on the platforms at the ends.

The minimum number of passengers per car is 15, but this exceptional figure only applies to the old three axle Belpaire cars, first pattern, of the Belgian State Railway.

The AV1 Purrey car, also with three axles, of the Orleans Railway, which has first class only, takes 26 passengers.

The Purrey car of the Italian State Railway, with two axles, has 24 seats, first and third class, and also standing-room for 10 passengers, together with a very large luggage compartment. In the other two-axle steam cars, the number of seats

(1) This number naturally does not include the eighty-five motor luggage-vans of the Italian State Railway.

varies between 32 and 41. In the two axle petrol cars, the number of seats is relatively greater; there are from 44 to 46 seats, except in the case of the Daimler car of the Austrian State Railway, where there are only 28 seats.

The two-axle accumulator car of the Bavarian State Railway contains 36 seats.

In the three-axle steam cars, series AV2-11, of the Orleans Railway, and in those of the Paris-Lyons-Mediterranean, there are 55 and 59 seats respectively.

The four-axle steam cars, excluding the narrow-gauge cars, contain 55 (cars MCCi of the Bavarian State Railway) or 66 seats (cars, series 85 and 86, of the Italian State Railway); the accumulator cars contain 66 (Belgian State Railway) or 80 (Saxon State Railway).

The comparison of the total weight, in working order, of automotor cars belonging to each of the different types, with the theoretical weight of ordinary stock, of equal capacity as regards number of seats and space available for luggage and mails, would have presented some interest. But the data we have received in this connection are incomplete, and moreover, there is an inevitable uncertainty in determining the theoretical tare corresponding to the standing-room and to the luggage and mail compartments, owing to the variable utilization of the latter. This comparison is, moreover, implicitly included in the more general comparison of the relative cost of automotor-car services and locomotive services, and so we need not discuss it separately and in detail.

Brake gear. — Hand brakes are fitted to all the automotor cars we are considering, and the brake acts on all the wheels of the two-axle automotor cars.

In the case of the cars with a separate motor truck, the hand brake operated from the driver's cab acts generally on the wheels of the truck; the other wheels are braked from the back platform or from the guard's compartment.

The continuous brake (compressed air or vacuum) is fitted to all the automotor cars except the following: the Ganz steam car and the accumulator car of the Bavarian State Railway; the accumulator car and the Daimler car of the Saxon State Railway; the four Daimler cars of the Wurtemberg State Railway; the Serpollet steam car and the Daimler car of the Austrian State Railway; the Daimler car of the Swiss Federal Railway.

Heating and lighting. — The steam cars about which we have received information, are all equipped with steam-heating apparatus, except the old Belpaire cars of the Belgian State Railway which have stoves for burning coal.

The petrol cars utilize the hot water obtained by cooling the motor, for heating the passenger compartments.

The accumulator cars have stoves for burning coal.

The large majority of the automotor cars we are considering, whether steam or petrol, utilize ordinary oil or paraffin lamps for lighting.

Acetylene is however used for lighting the inside of the following: two Ganz

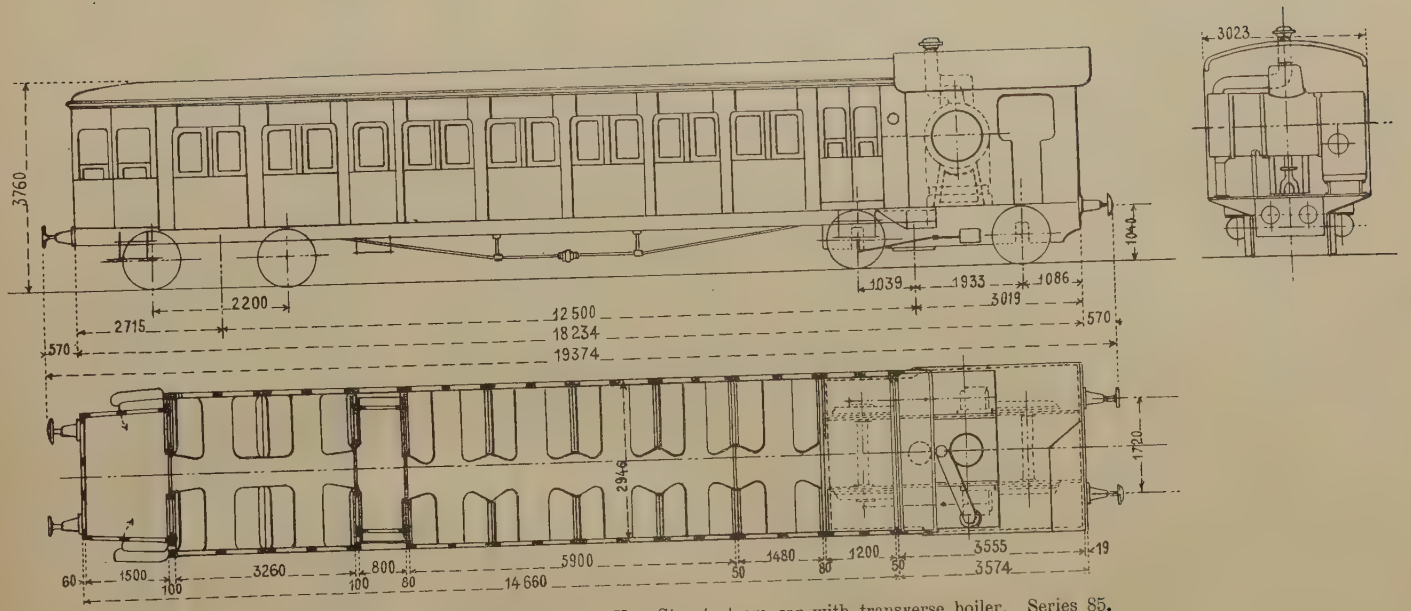

Fig. 5. — Italian State Railway. — Kerr-Stuart steam car with transverse boiler. Series 85.

steam cars of the Austrian Southern Railway; two Purrey cars of the French State Railway; the steam cars series 85 and 86 of the Italian State Railway.

Electric lighting is generally used in the accumulator cars, as well as on the three Purrey steam cars of the Italian State Railway; a battery is provided for the purpose.

Draft gear and buffing gear. — All the automotor cars considered are fitted with draft and buffing gear of the ordinary type, so that they can be coupled up with ordinary stock; the only exception is the one petrol car of the Swiss Federal Railway, which is intended to run always alone, and is not fitted with any draft or buffing gear.

We must also mention the benzo-electric cars, of the Weitzer type, of the Arad-Csanàd Railway, referred to above in connection with a trial run on a line of the Italian State Railway; these cars, although intended to run on standard-gauge lines, are fitted with central draft and buffing gear, being devised to run either alone or with special trailers.

Boilers of steam cars. — The standard type of locomotive boiler, with smoke tubes and a horizontal barrel, is used : on some of the four-axle cars (series MCC*i*) of the Bavarian State Railway; on the two series of the old Belpaire cars of the Belgian State Railway; and on the four-axle cars (series 85 and 86) of the Italian State Railway. The centre line of the boiler is on the longitudinal axis of the car and placed in the normal position, with the chimney in front, on the seventeen Belpaire cars of the Belgian State Railway and on the twelve cars of series 86, Kerr-Stuart type, of the Italian State Railway (fig. 4). On both of them the fire-door is on one side of the fire-box, instead of being in the back wall, so as to make it easier to attend to the fire in a space which is necessarily limited, and to make it easier for the driver, when only one man drives the engine, to see the track and the signals.

On the automotor cars, series MCCi (fig. 3) of the Bavarian State Railway, the boiler is in a longitudinal position, but the chimney is at the back; the fire is fed by means of a charging-cone which acts semi-automatically.

The three automotor cars, series 85 (fig. 5) of the Italian State Railway, have cross-boilers occupying the whole width of the cab on the motor truck. These motor trucks were designed and built by Messrs. Kerr-Stuart & Co., of London; this arrangement has the disadvantage, if used on lines with sharp curves, of altering the level of the water in the crown of the fire-box. The Italian State Railway has consequently decided on placing the boiler longitudinally, when repairs are being carried out; and this has already been done in the case of one of these cars.

Vertical boilers with smoke tubes are used on the Wurtemberg State Railway for the two-axle standard-gauge cars, series DW 5-14 (fig. 6) and for the two-bogie narrow-gauge car DWss 1; also, on the Italian State Railway, for the motor luggage-vans, series 60 (fig. 1).

The Wurtemberg State Railway uses for the above-mentioned cars boilers of the Kittel type (fig. 9); this boiler has its barrel enlarged at the upper part, like the

well-known vertical boilers of the automotor cars of the Great Western Railway. This enlargement is not only intended to give greater water-space and steam-space, but also to reduce the changes in the water-level. The fire-box is cylindrical, made of Fox corrugated plate; the two tube-plates are also treated similarly and connected by 330 tubes; 298 of these are ordinary tubes having a diameter of 24 to 28 millimetres ($^{15}/_{16}$ to 1 $^{3}/_{32}$ inches) 26 act as stays (diameter, 21 to 27 millimetres [$^{13}/_{16}$ to 1 $^{1}/_{16}$ inches]) and 6 are placed at the outer side of the set of tubes; the latter have a larger diameter (40 to 45 millimetres [1 $^{9}/_{16}$ to 1 $^{25}/_{32}$ inches]), in order to facilitate the access of the hot gases to the tubular superheater placed in the smoke box.

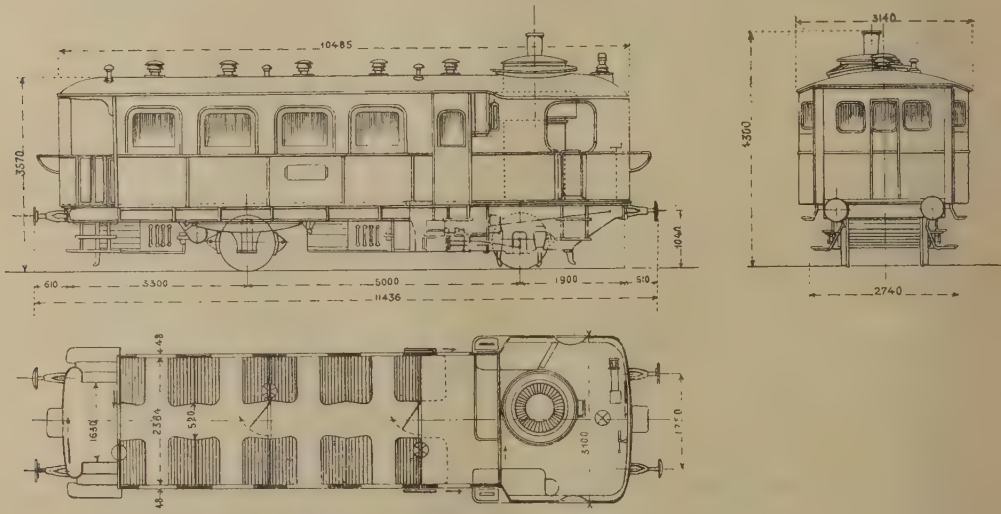

Fig. 6. — Wurtemberg State Railway. — Kittel steam car with vertical boiler.

The motor luggage-vans (series 60) of the Italian State Railway, have an ordinary vertical boiler (fig. 10) with fire-box, tubes and upper tube-plate of copper; twelve of these vans form an exception and are equipped with water-tube boilers, on the Komareck system; two others are fitted, experimentally, one with a vertical boiler with the upper part of the barrel enlarged (fig. 11) the other with a horizontal boiler of the locomotive type with tubes 1 metre (3 ft. 3 $^{3}/_{8}$ in.) in length (fig. 12).

The different types of water-tube boilers used on the cars described in the answers to the list of questions are as follows :

a) The Komareck type (fig. 13) with a cylindrical fire-box of the Fox corrugated type. Several concentric sets of curved iron tubes connect the upper flanged plate with the barrel. A superheater is placed in the large central tube leading the hot gases to the chimney. This type is used on the twelve motor luggage-vans of the

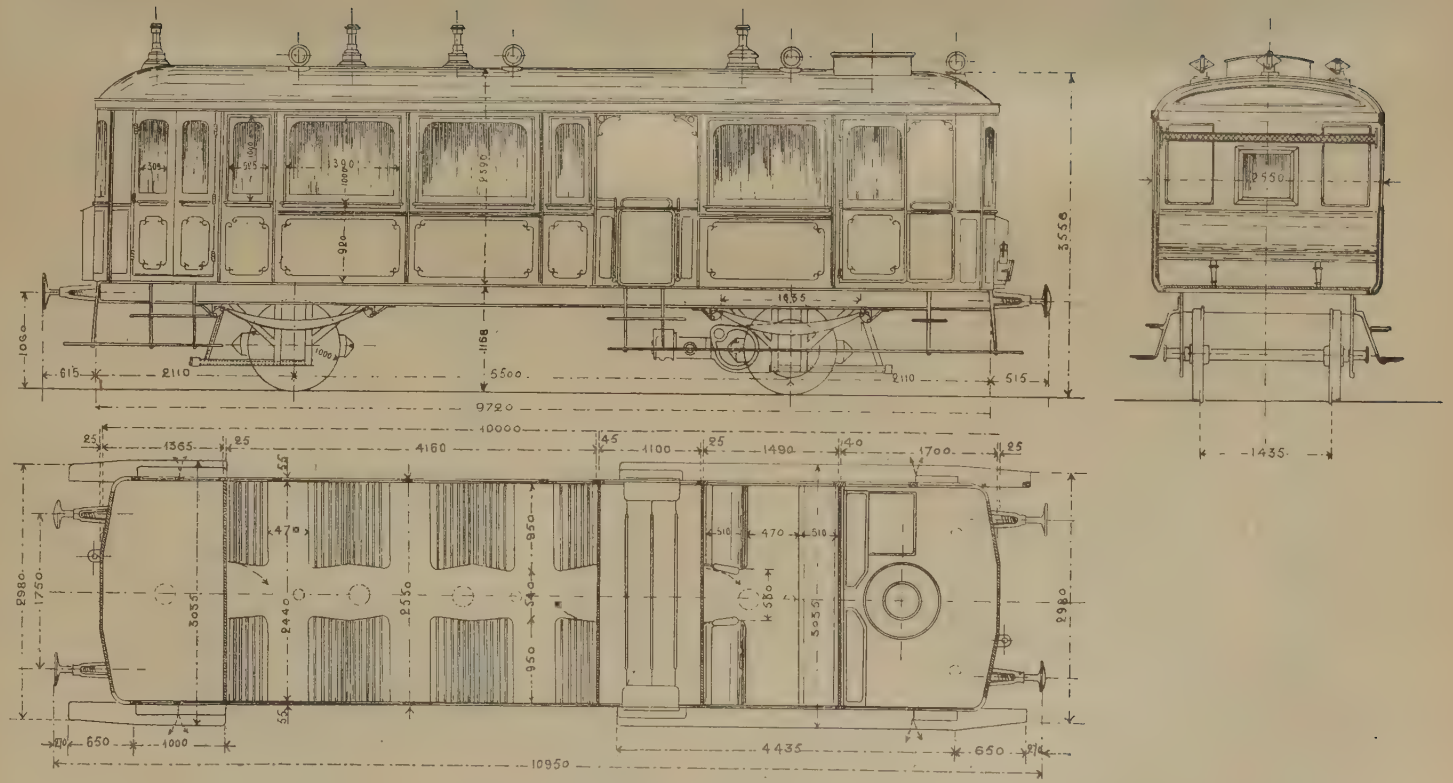

Fig. 7. — Bavarian State Railway. — Ganz steam car.

Italian State Railway, mentioned above, and on three cars of the Austrian State Railway. There are also some used on local railways in Lower Austria and on other secondary railways in Austria (see Mr. Ziffer's report to the Munich Congress, already quoted);

b) The de Dion type, used on the Ganz car of the Bavarian State Railway (fig. 7) and on the two cars of the Austrian Southern Railway. The boiler consists of two cylindrical rings placed one within the other and connected by a large number of very short water tubes, arranged radially and inclined upwards. The fuel is fed into the inside ring and the hot gases flow through the space in which the water tubes are (fig. 14). This is a rapid-steaming type, intended for use on low-powered cars;

c) The type with Field tubes, used on the three four-axle cars of the St. Quentin Railway;

d) The Turgan marine boiler, used on some of the four-axle cars, series MCCi, of the Bavarian State Railway;

e) The well-known Serpollet system, for the sudden formation of steam, with superheat and working at very high pressure (30 kilograms per square centimetre [427 lb. per square inch] and upwards), with very thick tubes, for accumulating heat in the metal; this type is used on four automotor cars of the Wurtemberg State Railway since 1897, on one of the Austrian State Railway and on two of the Paris-Lyons-Mediterranean Railway, which have just been withdrawn from service. The Saxon State Railway and the Swiss Federal Railway each had a Serpollet car in use formerly, now withdrawn from service;

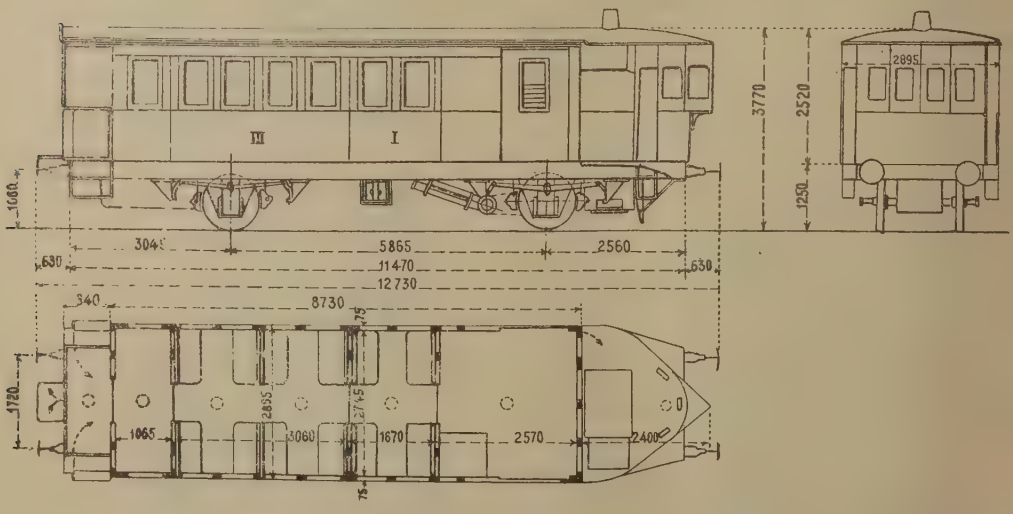

Fig. 8. — Italian State Railway. — Purrey steam car. Series 80.

f) The Purrey system, for the very quick formation of steam, with tubes of little thickness, arranged in coils, and with a steam drum at the top; it resembles the Serpollet type and is equally well known. This boiler is used on three two-axle cars, series 80, of the Italian State Railway (fig. 8), on two two-axle cars of the French State Railway, on eleven three-axle cars of the Orleans Railway, and on eighteen cars of the Paris-Lyons-Mediterranean Railway; six of the latter have two axles and twelve have three axles. They also give superheated steam, at a high pressure (20 to 24 kilograms per square centimetre [284 to 341 lb. per square inch]).

We must also mention the Stolz vertical boiler, used on the Prussian State Railway, which is mentioned in the works quoted, but about which we have received no direct information.

The superheating of the steam, which is inherent in the boiler systems of the Serpollet and Purrey types, is also used, to a limited extent, in the Kittel and Komareck boilers. The locomotive-type boilers of the four-axle cars of the Bavarian State Railway have a Schmidt superheater in the smoke tubes; the Turgan boilers, used on some of the same cars, also have superheater tubes.

Apart from the exceptionally-high pressures obtained in the boilers of the Serpollet and Purrey type, the working pressure in the other boilers varies from 12 to 16 kilograms per square centimetre (170 to 228 lb. per square inch), and reaches 18 kilograms per square centimetre 256 lb. per square inch) in the boilers of the de Dion type used on the Ganz cars.

As regards the dimensions of the grate and of the heating surface, the smallest are those of the de Dion boilers used on the Ganz cars of the Bavarian State Railway and of the Austrian Southern Railway : grate area, 33 square decimetres (3·55 square feet); heating surface, about 8·5 square metres (91·50 square feet).

Next come the Serpollet cars, with a grate area of 46 square decimetres (4·95 square feet) and a heating and superheater surface of 11 to 12 square metres (118·41 to 129·17 square feet).

The Kittel boiler of the Wurtemberg State Railway has a grate area of 51 square decimetres (5·49 square feet), a heating surface of 25·5 square metres (274·49 square feet) and a superheater surface of 9·5 square metres (102·26 square feet).

The Field boiler of the cars of the St. Quentin Railway has similar dimensions; the same can be said of the Komareck boiler of car 1101 of the Austrian State Railway; the other two, series 1001-1002, have a slightly larger grate area.

On all the other steam cars, the graet area varies between 67 square decimetres and 1·08 square metres (between 7·21 square feet and 11·63 square feet); the heating surface varies between 20 and 25 square metres (between 215·29 and 269·10 square feet) on the Belpaire and Purrey boilers, between 39 and 60 square metres (between 419·80 and 645·85 square feet) on the four-axle cars of the Bavarian State Railway and on the Italian State Railway (Turgan and locomotive-type boilers), and on the motor luggage vans of the latter (ordinary vertical boilers, Komareck type, and locomotive-type boilers).

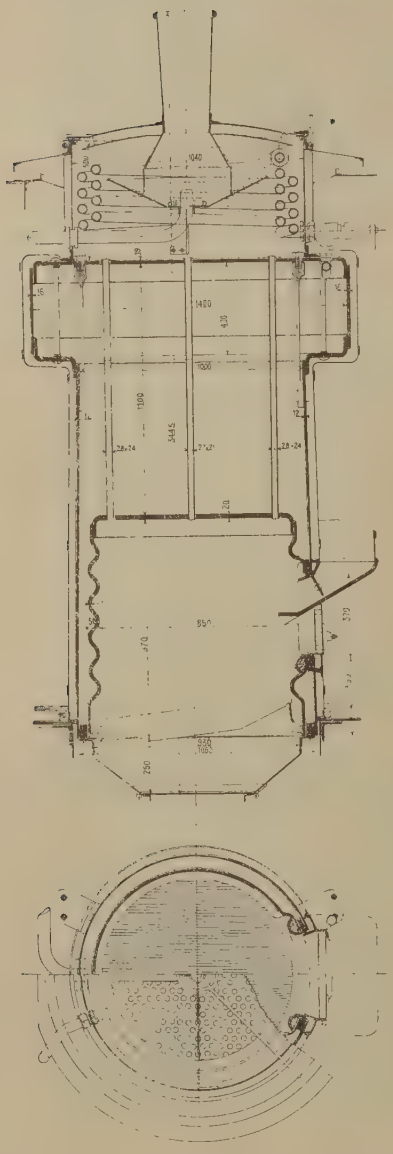

Fig. 9. — Wurtemberg State Railway. — Kittel vertical boiler for car. Serie D. W.

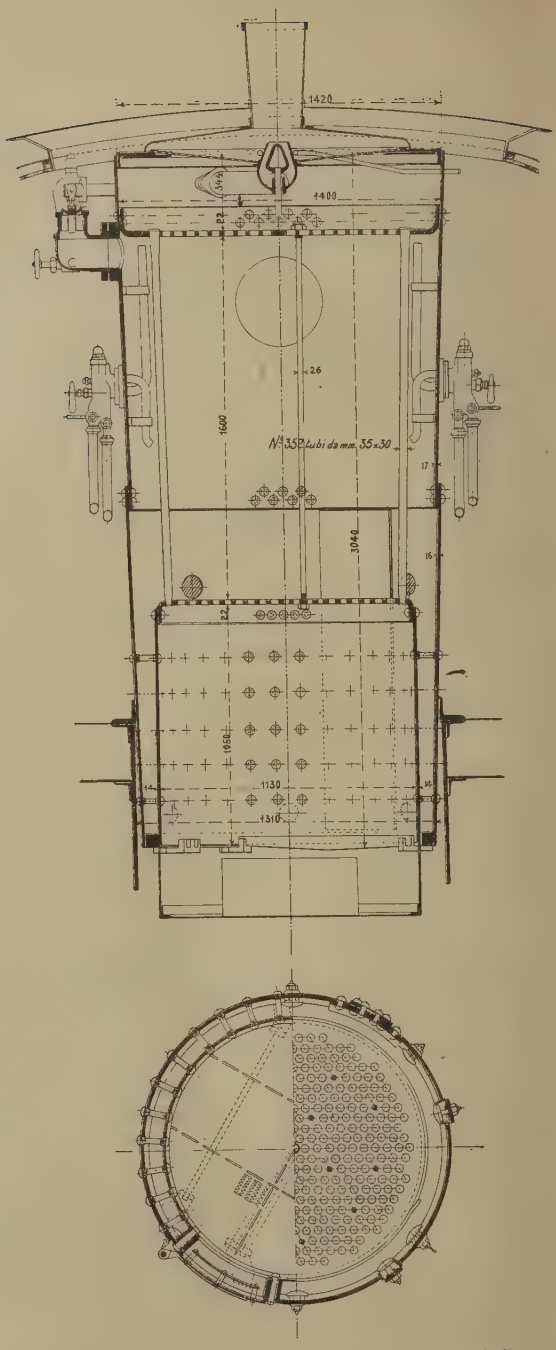

Fig. 10. — Italian State Railway. — Vertical boiler with smoke tubes for motor luggage-vans. Series 60. Original type.

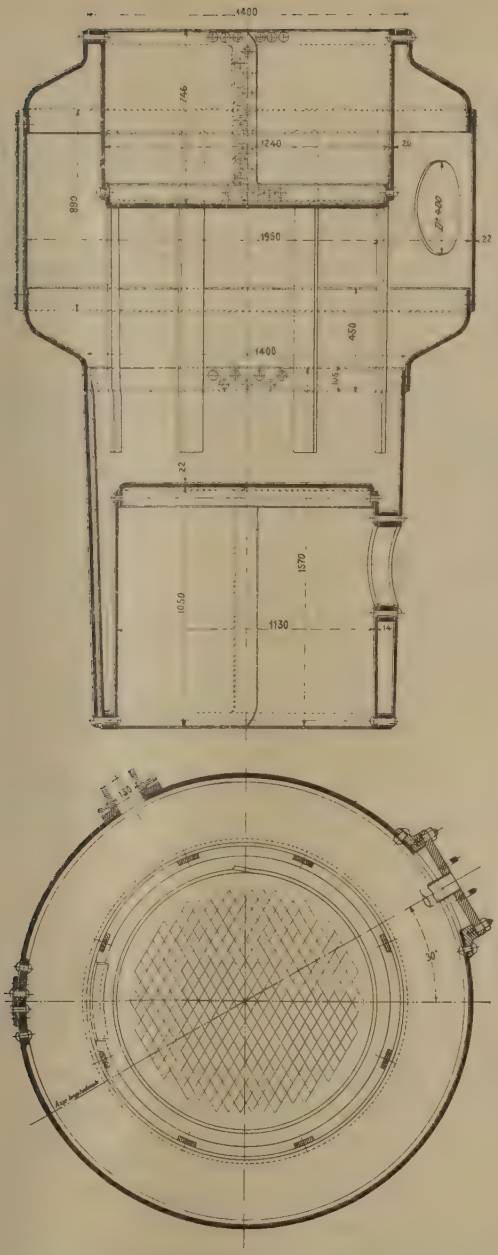

Fig. 11. — Italian State Railway. — Vertical boiler with smoke tubes for motor luggage-vans. Series 60. Modified type (now under trial).

The ratio between the heating surface and the grate area is rather limited in the Belpaire (old Belgian cars), Serpollet and Purrey types. It is included between 23 and 26 with the two former, while it is 24 or 32 with the latter, according to whether the superheater surface is included or not.

In all the other boilers considered, we find ratios similar to those found in locomotives; they are included between 35 and 60, not counting the superheater surface.

The fuel most generally used is still coal. In the case of the cars with de Dion boilers, the Bavarian State Railway always uses coke, while coal is always used on two other cars of the same type, belonging to the Austrian Southern Railway. Coke is exclusively used for the Purrey boilers. On none of the steam cars about which information has been sent to us, is heavy oil used, which is, however, utilized on the small locomotives of the Austrian State Railway (1). Paraffin was used on the Serpollet car of the Paris-Lyons-Mediterranean Railway, which is, however, no longer in use.

The semi-automatic feeding of the grates burning coal reduces the work of firing and makes it

(1) Heavy oil is also utilised on the Stoltz boilers of the Prussian State Railway. (See Guillery, *op. cit.*)

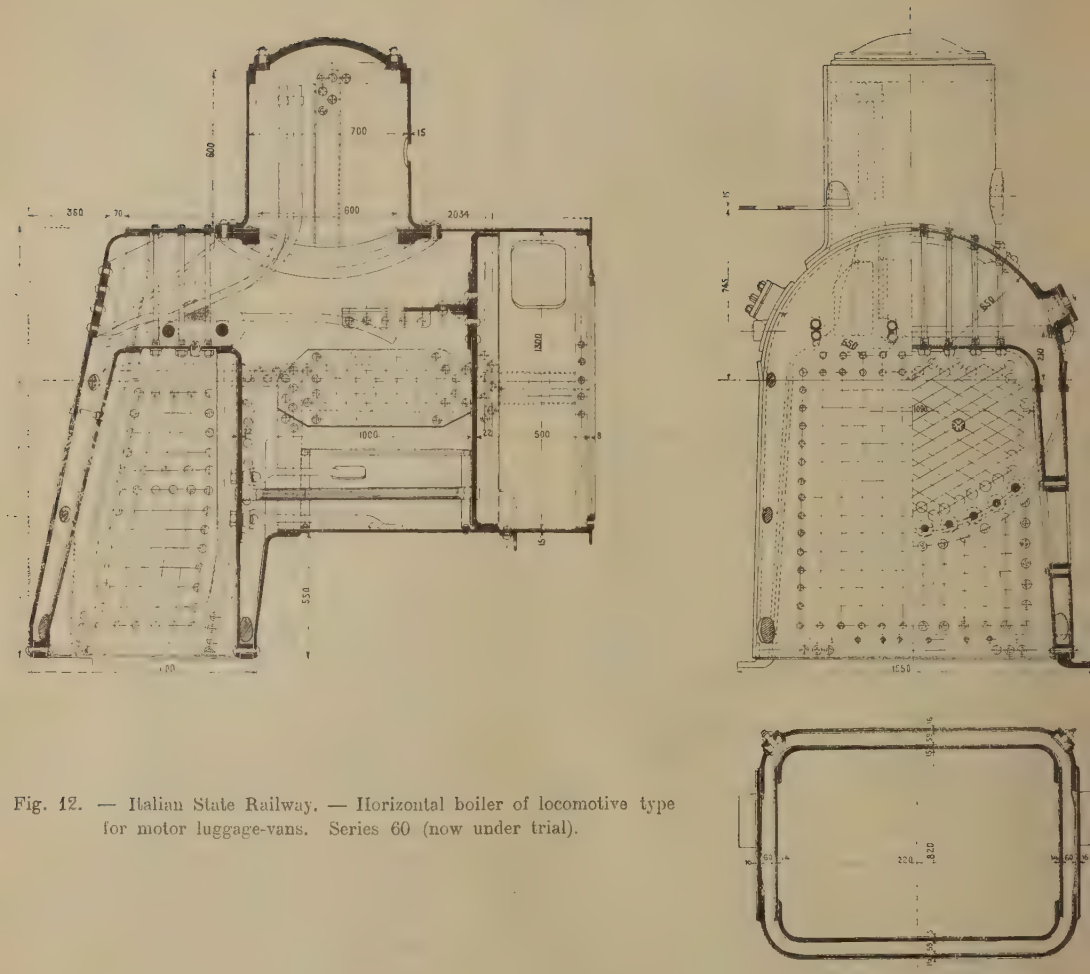

Fig. 12. — Italian State Railway. — Horizontal boiler of locomotive type for motor luggage-vans. Series 60 (now under trial).

easier for one man to run the engine; this is generally applied in the Purrey boilers and also, more recently, in the locomotive-type boilers of the four-axle cars of the Bavarian State Railway.

Feed-water pumps are used for the high-pressure boilers of the Serpollet, Purrey and de Dion types. They only work automatically in the Serpollet system, and partly in the Purrey system. All the other boilers have injectors.

Engine of the steam cars. — Single expansion, with two cylinders, is used in most

cases. The only exceptions are the de Dion motors on the Ganz cars and the motors of Purrey cars, which use double expansion; the former have two cylinders and the latter four. A special arrangement exists in the Bavarian cars with four axles, in which each of the two cylinders incloses two piston heads in juxtaposition, each acting with a separate rod and cross-head on one of the two coupled axles (fig. 3).

Piston valves are used on the four-axle cars of the Bavarian State Railway and on the motor luggage-vans of the Italian State Railway; all the other cars have flat slide valves.

The most usual system of transmission is that of the locomotive type. Spur gearing is used on the Ganz cars, and chain transmission on the Purrey cars. In these cases the gear is protected by a *gear case*.

The power of the steam cars, taken as a whole, varies between a minimum of about 35 horse-power (de Dion motor of the two-axle Ganz cars of the Bavarian State Railway and the Austrian Southern Railway) and a maximum of about 180 to 200 horse-power (four-axle cars of the Bavarian and Italian Railways).

Mechanism of cars with motors of other systems. — The only type of internal-combustion motor used on the cars considered in the answers to the list of questions is, as we have already seen, the Daimler petrol motor, with four cylinders, with a transmission consisting of two or more pairs of gear wheels. It is of 30 horse-power.

We hear that a few builders are at present investigating the application of motors burning heavy oil or petroleum residue direct.

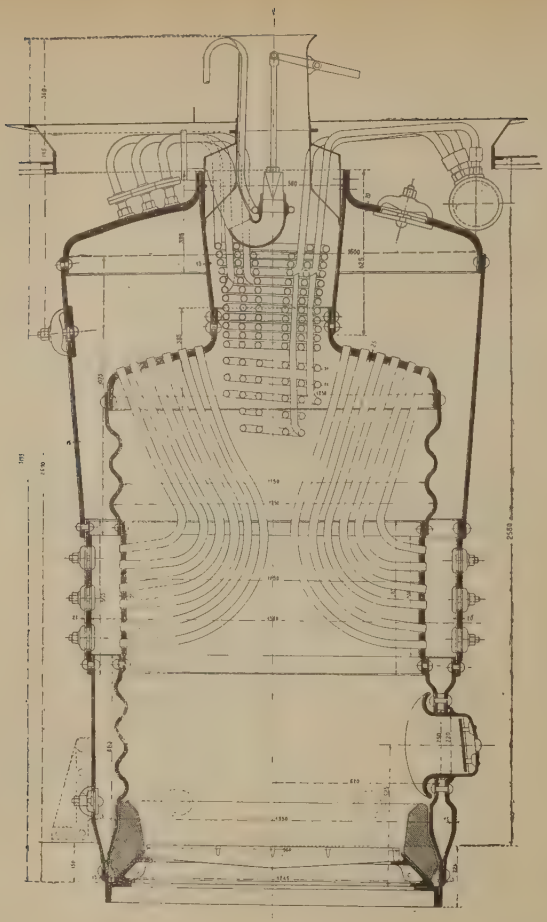
As regards systems with an internal combustion motor and electric transmission (benzo-electric, mixed, etc.) we refer our readers to what has been stated above.

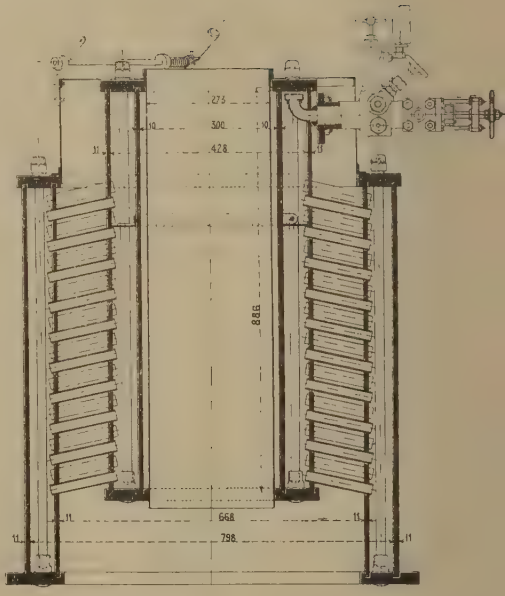
No characteristic peculiarity has to be mentioned in the case of the accumulator cars given in the table in appendix II.

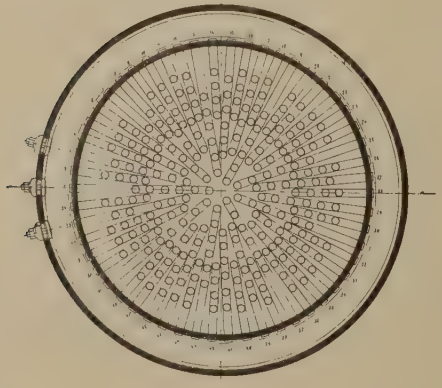
Location of the cab for the driver, provision for travelling backwards. — When considering automotor cars, we encounter the problem of the means of control, as regards the possibility of running in either direction, a problem which is of considerable importance as regards the utilization of the cars.

The most satisfactory solution is evidently that in which perfect symmetry is attained, with identical cabs at each end of the car, each equipped with the same controlling gear. This solution, which makes it unnecessary ever to turn the car, while running in either direction under absolutely the same conditions, is adopted generally in the accumulator cars and in the Daimler petrol cars; but it cannot be attained in the case of steam cars.

There is a fairly considerable number of steam cars, in which the problem of running in either direction has been left out of consideration. These cars only have one cab at the one end, and no means of control at the other end; they must accordingly be turned at the end of every journey. This class includes the old







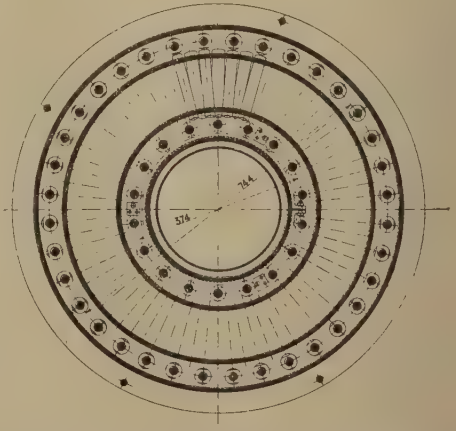


Fig. 13. — Italian State Railway. — Komareck vertical water-tube boiler for motor luggage-vans. Series 60. (now under trial).

Fig. 14. — Austrian Southern Railway. — de Dion-Bouton water-tube boiler for the Ganz car.

Belpaire cars, first pattern, of the Belgian State Railway, and the motor luggage-vans (series 60) of the Italian State Railway, which can be turned on the ordinary station turn-tables, as their wheelbases are short; also the Belpaire cars, second pattern, of the Belgian State Railway, the Serpollet cars of the Paris-Lyons-Mediterranean Railway, the Ganz cars of the Austrian Southern Railway and all the Purrey cars, which having wheelbases which always exceed 5·50 metres (18 feet) require locomotive turntables.

It is however interesting to note the method adopted by the Orleans Railway, which turns the Purrey cars, which have three axles, two forming an independent motor truck, by means of an auxiliary traverser, which can receive the third axle of the car and runs on a circular track concentric with the turn-table which has a diameter of 4·400 metres (14 ft. 5 in.).

The solution sometimes adopted in England, which consists in utilizing a long motor car with the engine in the middle, or else in a small train formed with a small locomotive which is placed between two carriages and has a rather smaller loading gauge than the latter, is not applied by the administrations on the Continent which have sent answers to our list of questions.

All the other automotor cars enumerated in the table, appendix II, are steam cars having a completely-equipped cab at the end where the boiler is, and at the other end an auxiliary cab, or a simple platform equipped with a certain number of controlling apparatus. This post is occupied, when running backwards, by an employee who generally has available a valve for operating the continuous brake, a steam or compressed-air whistle and a lever for closing the regulator. The four-axle cars (series 85 and 86) of the Italian State Railway were at first fitted with a lever which made it possible, by means of a chain, to open or close the regulator; but the opening action has been done away with.

Electric bells or speaking-tubes are generally provided in cars of this kind to enable the driver in charge of the boiler and engine to communicate with the employee on the end platform when the car is running with the engine at the back.

An exception is formed by the small two-axle Serpollet and Kittel cars, of the Wurtemberg State Railway, on which there is no auxiliary post of control at the opposite end to that where the boiler is; there is only a whistle and an extra brake valve. When the car is running backwards, the employee on the leading platform does not intervene except in case of danger, the driving being normally entrusted to the driver, who can see the track and the signals thanks to the limited length of the car and in the case of the Kittel cars thanks to the suitably wider section of thecab.

Use of small locomotives instead of automotor cars. — According to the answers we have received, the Bavarian State Railway and the Austrian State Railway have designed new types of locomotives, in order to operate services of this kind either jointly with automotor cars or in order to replace them.

The Bavarian State Railway at present has in use forty single-expansion locomo-

tives, series PtL $\frac{2}{2}$ particulars of which are given in the table, appendix II; twenty more are being built. These locomotives are of two different types designed and built by the firms Maffei and Krauss respectively.

The boilers are of the locomotive type, with Schmidt superheater in the tubes and semi-automatic feeding of coal, by means of a charging-cone; the boiler of the Maffei locomotives is the same as that used on the four-axle cars of the Bavarian State Railway; the same can be said of the engine, which also has the peculiar arrangement of cylinders each with two pistons working in opposite directions.

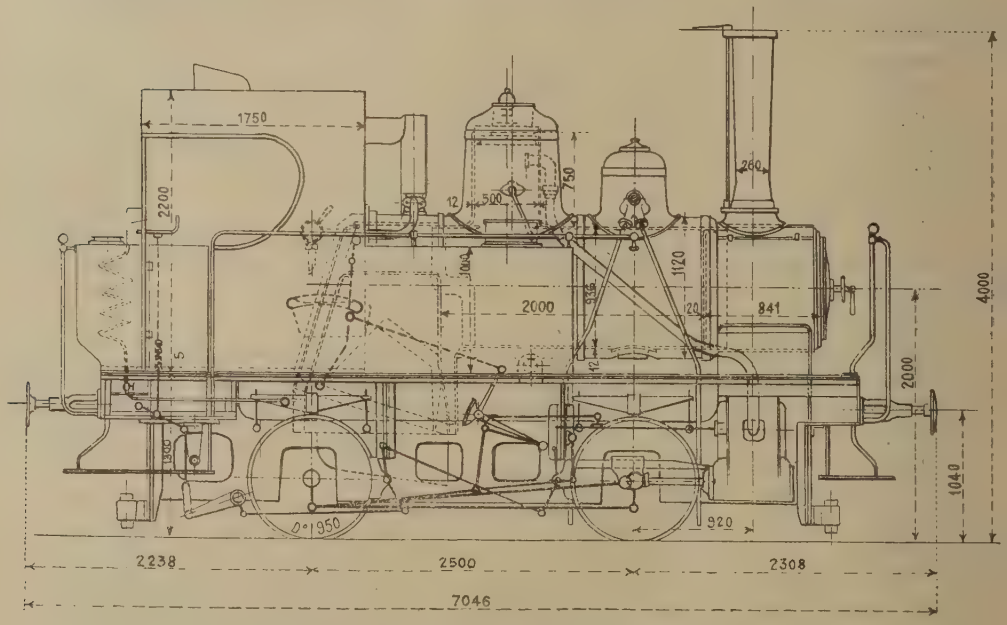

Fig. 15. — Austrian State Railway
Tank locomotive series 86 burning petroleum; the Holden system.

In the locomotives built by the firm Krauss, the connecting rods act on an intermediate shaft which by means of cranks transmits the motion to the coupling rods of the two axles. Particulars are given in Mr. Ziffer's report to the Munich Congress. The weight of these locomotives belonging to the Bavarian State Railway is 18·5 tons (18·2 English tons) empty and about 22·5 tons (22·1 English tons) in working order. The fuel used is coal.

The locomotives of the Austrian State Railway also have two axles (one driving, the other coupled). They belong to two series (185 and 86); the second has a rather more powerful boiler (fig. 15) : the grate area is 65 square decimetres

(7 square feet) and the heating surface 28·7 square metres (308·94 square feet). Petroleum residues are used for firing, the burners being of the Holden type; coal can be used as auxiliary fuel. These locomotives use saturated steam; there are two cylinders and double expansion is used.

The French State Railway has for a long time been using luggage-van locomotives, which are really true tank locomotives with a compartment for luggage and for the guard. They are of two series, both with two coupled axles; they practically only differ in the dimensions of the boiler, and in the number of carrying axles (one or two).

Several of the administrations which use automotor cars also utilize, for similar services, old tank locomotives with two or three axles, weighing 20 to 27 tons, of ordinary construction.

The same applies to some old tank locomotives utilized for local services by three of the administrations which inform us that they are not using any automotors cars: the old French Western Railway, the Norwegian State Railway and the Aussig-Teplitz Railway; particulars of these locomotives are given in the table, appendix II.

II. — **Organization of the service. Modus of working.**

Use of trailers. — The Daimler petrol cars, being of low power, are used exclusively without trailers.

The accumulator cars and the Ganz steam cars of the Bavarian State Railway, and the Serpollet car of the Austrian State Railway, are also generally used without trailers.

All the other automotor cars are used either alone, or, and more generally, with trailers; the maximum number of trailers used is two or three with the Serpollet, Purrey and Ganz cars of the Austrian Southern Railway and attains four to seven with the cars having a more powerful boiler, such as the Belpaire cars of the Belgian State Railway, certain series of the cars with Komareck boiler, the cars (series 85 and 86) and the motor luggage-vans (series 60) of the Italian State Railway.

The luggage-van locomotives of the French State Railway haul light trains, which may include up to sixteen axles.

The continuous brake is used in most cases on the light trains formed of one automotor car with one or more trailers.

Intercommunication between the automotor car and the trailers by means of gangways for the use of the train staff, is only provided on the Wurtemberg State Railway, the French State Railway (only on the light trains hauled by the luggage locomotives) and on the Paris-Lyons-Mediterranean Railway.

The four-axle automotor cars of the Bavarian State Railway are equipped with gangways for such intercommunication, but they are not used.

All the trailers used by the different administrations mentioned are of ordinary type and present no peculiarity.

The Italian State Railway uses either ordinary carriages with two axles, or bogie carriages of a light type and large capacity, specially designed for trains hauled by automotor cars or luggage-van locomotives. A certain number of these carriages are now in use. The typical light train consists of an automotor car (series 85 or 86) with one of these trailing bogie carriages, or of a motor luggage-van (series 60) with two trailing bogie carriages.

No administrations allow automotor cars or small locomotives to push other cars ; this practice is adopted by some of the English companies, in order to avoid shunting operations at the end of a journey.

Maximum speed authorized. — This varies, according to type of car, between 40 and 75 kilometres (25 to 46·6 miles) per hour.

In the case of the Kittel and Serpollet cars of the Wurtemberg State Railway, which are not turning at the end of a journey and which have no auxiliary cab with controlling gear at the opposite end to that where the engine is, this is reduced to 50 kilometres (31 miles) per hour when running backwards.

In the case of the motor luggage-vans (series 60) of the Italian State Railway, which as already stated are normally turned at the end of a journey, it is prescribed that the speed or 18 kilometres (11·2 miles) per hour must not be exceeded in the *exceptional* case of running backwards.

Number of traction agents on automotor cars with or without trailers. — When accumulator cars (even with trailers) or petrol cars are used, the management is entrusted, as a rule, to one driver and to one conductor or guard.

The management is also entrusted to one driver and to one guard in the case of the passenger services operated on the lines which use Serpollet, Purrey and Kittel steam cars, with or without trailers.

The rule of entrusting the management to one single driver, with the eventual intervention of the guard, is not always adopted in the case of steam cars of other types.

Thus the Ganz cars are managed by one single driver and one guard on the Bavarian State Railway, where they always run without trailers, while there are two traction agents, driver and fireman, and one guard on the trains of the Austrian Southern Railway, where the cars always haul two trailers.

The Komareck cars, series 1001-1002, of the Austrian State Railway, which generally run without trailers, and occasionally with one trailer, have two employees on them, driver and guard, while the work is carried out by three men, driver, fireman, and guard on the Komareck car 1101, which is rather more powerful, and belongs to the same railway ; it generally hauls three ordinary carriages.

The four-axle steam cars of the Bavarian State Railway have one or two traction agents, plus the guard, that is two or three men altogether, according to the composition of the train and the conditions of the service.

The old Belpaire cars of the Belgian State Railways had two traction agents.

The ministerial regulations concerning the service of the automotor cars (series 85 and 86) and of the motor luggage-van (series 60) of the Italian State Railway authorize the use of one sole traction agent and one guard under certain conditions. But up till now, the engines have been managed by a driver and a fireman owing to temporary difficulties and service conditions which have made it necessary to use them, in most cases, to haul comparatively heavy trains which should have had locomotives.

In principle, the possibility of having one sole traction agent, which is one of the most important factors in reducing the working expenses of automotor cars, depends on several conditions which it is not always possible to realize fully when using steam engines.

As regards the design of the automotor car, it is above all necessary that the driver should be able to see the track and the signals well, while he must at the same time be able to attend to the boiler and the engine. Every effort must therefore be made to reduce this attention to a minimum, either by the use of semi-automatic stoking gear, or by the use of liquid fuel.

The latter solution, which has been investigated by the administration of the Italian State Railway, at present still encounters difficulties in the case of the small boilers of the locomotive type and of the vertical boilers. A trial of this kind is being carried out on the small locomotives (series 185 and 86) of the Austrian State Railway, as mentioned above.

The semi-automatic feeding of the fire is effected on the Purrey cars (with coke) and on the four-axle cars and the small locomotives of the Bavarian State Railway, having Maffei or Krauss boilers, which burn ordinary coal. Other trials of this kind have been made by other administrations, for instance by the Austrian State Railway on the small locomotives series 85.

The reduction of the traction staff of steam cars to one single driver is also possible, apart from the conditions of the design mentioned above, when the working conditions reduce to a minimum the work the boiler requires, so as to limit the variations of the water-level while running, and to make it possible only to add fuel to the fire during a stop or at long intervals. These conditions occur when very small loads have to be hauled, when the profile of the line is easy, when stops are not far apart, when the journeys are short and when the line, not having too much traffic on it and not being complicated by too many signals, junctions, etc., does not demand too continuous attention from the staff.

When the car, with or without trailers, is managed by one single driver, it is evidently indispensable that the guard or conductor or one of them, it there are several, should be able to stop the car should this become necessary. He must therefore know how to manipulate the controlling gear of the engine, in order to be able to stop the car even if the conti- nuous brake were absent or did not work.

The conditions of design and of service making it possible to reduce the traction

staff to one single man being realized, we will now examine the conditions which have to be satisfied so that a given train, even if there are several trailers, only requires one employee (guard or conductor) in addition to the said driver.

Two cases have to be considered, according to whether the nature of the service or the location of the luggage compartment if there is one, makes it necessary for the guard to be normally on the automotor car, or whether he can pass on to the trailers.

In the first case, it is not necessary to have intercommunication; but then having only one guard makes it necessary to have the continuous brake, as there will be no employee at the tail of the train to attend to matters should a train-break occur.

In the second case, intercommunication is indispensable, to allow the guard to pass from one end of the train to the other, and if necessary to operate the controlling gear of the motor in order to stop the train.

It is evident that when the number of trailers exceeds two or three, it becomes difficult to have only one guard, taking into consideration the requirements of a passenger service; in such cases, it will generally be necessary to have two men, in addition to the driver. The one will be on the automotor car itself while the other will be in the tail of the train.

The same considerations apply in the case of light trains hauled by small locomotives instead of automotor cars.

It would be interesting to examine whether it is better to entrust the head duties, that is to say, the responsibility as regards the ordering of the operations, to the guard or one of the guards, or to the driver. In the latter case, the other employees would be simple guards, only attending to the passenger service, and capable of stopping the automotor car in cases of necessity.

The second system is sometimes adopted in the case of electric traction, whether accumulators be used or current from outside.

In the case of automotor cars with steam or internal-combustion motors, the first of the two systems is generally preferred, consideration being paid to the more extended technical knowledge the driver must have, as well as the considerable work and attention demanded of him; *a fortiori* when the driver must also act as fireman.

Besides it is a question of degree, which can be solved differently according to the local conditions and the qualities of the staff which is available.

Another question of detail, which can also be solved in different ways, is question 4, chapter II, of the list of questions (see appendix I), which refers to automotor cars having the whole steam engine at one end, and an auxiliary look-out with bell, whistle, brake, etc., at the other. When there is only one traction agent, the general practice when the car runs backwards is that the driver remains in his cab and that the front cab is occupied by the conductor.

In the case of two traction agents and one conductor, various solutions are adopted.

On the Komareck car 1101 of the Austrian State Railway, when running backwards, the driver and fireman both stop in the engine cab, and the conductor goes on to the front platform.

With the Belpaire cars of the Belgian State Railway which are normally turned at the end of the journey, the fireman, in the *exceptional* case of running backwards, goes on to the front platform in order to look out at the track and the signals, and the driver remains in his cab.

With the automotor cars (series 85 and 86) of the Italian State Railway, when looked after by three men (driver, fireman and conductor), the fireman remains in the engine cab when running backwards; but the driver goes into the other cab, where he has available appliances for operating the brake and the whistle, and for closing the regulator, as well as a bell system for communicating with the fireman.

As an example, we quote the rules of the Austrian State which have to be observed in order that one single traction agent may be used on automotor cars or small locomotives :

" It is allowed to use small automotor cars and small locomotives managed by one single traction agent when the local circumstances are suitable, and subject to the following conditions :

" *a*) It is forbidden to feed the fire while running if the fire-door is opened;

" *b*) It must be possible to observe from the driver's post both the track and the apparatus which it is necessary to watch while running;

" *c*) There must be a passage leading from the driver's cab, or from the locomotive, to the rest of the train;

" *d*) An employee on the train, apart from the driver, must have the training of a fireman;

" *e*) In each case, the authorization to use one single traction agent is submitted to the decision of a local commission. "

Particulars of the lines operated. — As a rule, the automotor cars are utilized on level lines or on undulating lines with medium gradients of rather limited length.

As regards accumulator cars, we have no information on the subject except as regards the Saxon State Railway, which uses them on the Dresden-Pirna line, which is 17 kilometres (10·5 miles) long and has a maximum gradient of 3 per mil.

The Daimler petrol cars run on lines which have gradients attaining 16·6 per mil, over a length of 2·7 kilometres (1·7 miles) (Pirna-Amsdorf line, Saxon State Railway). There is also a 10 per mil gradient 4·3 kilometres (2·7 miles) long on the Amsdorf-Kamenz line (24·800 kilometres [15·4 miles]).

The Memmingenen-Rossbach line is 53 kilometres (33 miles) in length and has a maximum gradient of 8 per mil.

The chief runs now made *in current practice* by the steam cars of the different administrations are given below in table I.

Table I.

[1] Maximum for the Mühlacker-Backnang line (see table I), 20 tons (19·7 English tons); for the Böblingen-Stuttgart line, 35 tons (34·4 English tons).
[2] On the Alais-Ardoise line (see table I), the automotor cars run without trailers.
[3] At present the service has been stopped, owing to the greatly-increased passenger traffic.

Weight and composition of trains hauled by automotor cars. — The information collected on the subject of the weight hauled, the composition and the inclusive speed of trains hauled by automotor cars, as at present used in current practice, are given in table II.

Daily and yearly mileage of the automotor cars and locomotives, coefficient of utilization. — The Bavarian State Railway, which has eight steam cars, in use from 1904 to 1908, and one accumulator car, dating back to 1901, has not given the average mileage *per day of work*, as the service of these automotor cars is very variable, and not yet definitely organized The average distance run *per year*, *per existing unit*, varies between 12,000 and 20,000 kilometres (7,450 and 12,400 miles).

The Saxon State Railway utilizes the one Daimler car and the accumulator car, built in 1904, for services of 109 and 56 kilometres (67·7 and 34·8 miles) per day respectively. There is no service on holidays. The annual mileage is not given; locomotives act as reserve. The Serpollet car which started working in 1903 was withdrawn in 1906.

The four Daimler cars of the Wurtemberg State Railway were working from 1896 to 1902; two were normally utilized in the service and two served as reserve, in case of repairs, etc. The distance run by the cars in use averaged 224 kilometres (139 miles) per day; there was no service on Sundays; the annual distance run per unit was 33,600 kilometres (20,880 miles).

The four Serpollet cars of the same railway were running from 1897 to 1902; two were used every day and two served as reserve, in case of repairs. The new cars with the Kittel boiler were built 1905-1907; eight or nine are normally in use. The mean annual distance run by each of the Serpollet and Kittel cars is 24,900 kilometres (15,472 miles).

The three Komareck cars of the Austrian State Railway, built 1905-1906, are utilized at three different points of the system, for services of 132, 113 and 153 kilometres (82, 70 and 95 miles) per day. The annual distances run were 29,940, 23,306 and 30,000 kilometres (18,604, 14,482 and 18,640 miles) respectively; the coefficients of utilization are thus 62, 58 and 56 per cent.

The Serpollet and the Daimler car of the same railway are in use since 1902, and are used in one and the same service, in which the distance run is 75 kilometres (46·6 miles) per day of service. The distances run in the year 1907 were 7,893 kilometres (4,905 miles) by the first car and 16,962 kilometres (10,540 miles) by the second car (coefficient of utilization, 29 and 61 per cent).

The two Ganz steam cars of the Austrian Southern Railway are utilized for a service of 90 kilometres (56 miles) per day each. On the average, there are 1·3 units at work, and 0·7 unit under repair; the distance run in the year 1907 was 22,116 kilometres (13,742 miles) per car.

On the Belgian State Railway, the old Belpaire cars, first pattern, were utilized for a service requiring nine units in which the average daily run was 95 kilo-

metres (59 miles) each; the distance run per year was 13,900 kilometres (8,637 miles) per unit.

The French State Railway utilizes its two Purrey cars, built in 1904, for a couple of trains on a total length of 108 kilometres (67·1 miles), there and back; the service is operated by one of the two cars, the other acting as reserve.

On the Orleans Railway, nine of the eleven Purrey cars, built 1902-1905, are in use every day, running an average distance, according to the time-tables (1), of 119 kilometres (73·9 miles) per day. The mean annual distance run is 28,000 kilometres (17,400 miles) per unit, and this represents a coefficient of utilization of 65 per cent.

The average run per day of work of the twenty Serpollet and Purrey cars of the Paris-Lyons-Mediterranean Railway, built 1903-1907, is 108 kilometres (67·1 miles); definite data as to the annual mileage per unit are not yet available.

The three cars with Field boilers used on the St. Quentin Railway, which started in 1907, run 110 to 150 kilometres (68·4 to 93·2 miles) per day, according to season; the average is 43 kilometres (26·7 miles) per day per unit.

The Daimler car started in 1902 by the Swiss Federal Railway normally runs twenty-five days per month, running 92 kilometres (57·2 miles) per day.

The automotor cars of the Italian State Railway, built 1904-1907, are utilized according to time-tables which give an average of 87 kilometres (54·0 miles) per day. The annual mileage per unit has up to the present been limited by the frequent changes made in the programmes of utilization; these changes were in most cases made necessary by the quick and unexpected growth in the number of passengers. At the depots where the service remained more regular, the annual distance run by each unit has varied between 13,000 and 33,000 kilometres (8,080 and 20,500 miles).

The small locomotives which most resemble automotor cars, from the point of view of the services they are designed for, are, as already stated, these of the Bavarian State and the Austrian State railways, built respectively in 1904 and 1903-1905, and the luggage-van locomotives of the French State Railway, which were built in 1885. These run on all the lines of the system. The former are generally utilized on secondary railways, with gradients which attain 25 per mil on a length of about 4 kilometres (2·5 miles) (Bavarian State Railway, branch from Bodenwöhr to Neuenburg).

The annual average mileage of the Bavarian State locomotives amounts to 48,000 kilometres (29,830 miles).

In the case of the two small Austrian locomotives, this figure was 21,500 and 25,200 kilometres (13,360 to 15,660 miles) in 1907, the average distance run per day of work being 110 kilometres (68·4 miles).

---

(1) The automotor-car and locomotive time-table of the Belgian, French and Italian railways generally include the days of washing, which accordingly affect the determination of the mean distance run per day, while these are not included in the corresponding time-tables of the other countries.

The luggage-van locomotives of the French State Railway run on the average 25,000 kilometres (15,530 miles) per year.

It must be observed, as far as the Austrian State locomotives are concerned, that owing to their very limited number, it is only the question of a trial, and that the luggage-van locomotives of the French State Railway represent a type which is already old and does not appear very well suited to existing conditions; and this probably explains their limited utilization.

The annual mileage of the forty small Bavarian locomotives is, on the other hand, satisfactory and can be compared with the figures for the ordinary passenger locomotives, while the annual mileage of the automotor cars of all systems is materially lower.

The *coefficient of utilization*, that is to say, the ratio between the number of days of work per year and the total number of days in the year (or else the ratio between the distance actually run per unit per year and the theoretical annual mileage represented by 365 times the daily time-table run), can be estimated at at least 72 to 75 per cent in the case of ordinary locomotives; according to the information collected it is materially lower in the case of automotor cars (29 to 65 per cent).

Information concerning the different methods of utilization from the point of view of working (questions 12 to 16 of chapter II of the list of question). — The use of small train units gives rise to certain problems which do not arise when ordinary locomotives are used.

Thus the runs made by means of automotor cars are considered as made *with a limited number of seats*, and are accordingly marked in a special manner in the time-tables by the following administrations : the Wurtemberg State Railway, the Austrian State Railway, the Orleans Railway and the Swiss Federal Railway. As a general rule, the public is also informed of them, in the time-tables, by the Austrian Southern Railway and the Italian State Railway, but they are not considered as being with a limited number of seats.

The Saxon State Railway formerly indicated in the time-tables what runs were effected by automotor cars, but that is no longer done now. No indication is given in the time-tables of the Bavarian State Railway and of the French State Railway.

The substitution of a locomotive for the automotor car in cases of a sudden rush of passengers is practised by many administrations, for instance the Wurtemberg State and the Austrian State railways, which consider the trains hauled by the automotor cars as trains with a limited number of seats. The French State Railway starts an extra train.

The administration of the Paris-Lyons-Mediterranean Railway distinguishes between three classes of trains hauled by automotor cars; namely, TA 1, TA 2, TA 3.

The trains of the first class are assimilated to the stopping trains, without limitation in the number of seats; they are utilized for carrying parcels and if there is

much traffic a locomotive is used. The two other classes are considered as trains with a limited number of seats; one is utilized for passengers, luggage and dogs, while the other carries passengers only.

As a rule, the automotor cars are used for services either without connections, or connecting with ordinary trains. The Bavarian State Railway alone used them exclusively for local services without connexions.

As regards the programme of utilization, two cases have to be considered : use on main lines and use on secondary lines.

Automotor cars are used on secondary lines by all the administrations considered, except by the Bavarian and the Saxon State railways. The most usual system of utilization consists in runs sandwiched between the ordinary trains hauled by locomotives. On the Austrian State, the Orleans and the Swiss Federal railways, automotor cars are simply utilized in lieu of existing trains carrying but little traffic; while they used for special supplementary runs on the Wurtemberg, the Austrian Southern, the French State and the Paris-Lyons-Mediterranean Railways.

On the Italian State Railway, instances of both systems of utilization are to be found.

The use of automotor cars for the *complete* service of passengers on certain secondary or branch lines is practised on the Belgian State Railway (Belpaire car), the Paris-Lyons-Mediterranean Railway and the Italian State Railway. The small locomotives of the Bavarian State Railway and the luggage-van locomotives of the French State Railway are utilized in the same way. This system of working does not as yet exist on the Orleans Railway, but its application is contemplated.

When the complete service of a secondary line is effected by means of automotor cars, there are always goods trains for slow freight, the parcel and live-animal traffic being carried on the automotor trains, or else by special trains hauled by locomotives if required.

This method of working is not however suitable in the case of a continuous cattle-traffic requiring a number of trucks, too heavy for an automotor car to haul, but not heavy enough to justify the expense of trains specially put on and hauled by locomotives.

The utilization of automotor cars on main lines, in order to improve local communications by *supplementary* runs sandwiched between ordinary passenger trains, is effected by the administrations of the Bavarian State Railway, the Saxon State Railway (which however does not think of extending this application, which is very limited), the Wurtemberg State Railway, the Orleans Railway and the Italian State Railway. In these cases, the automotor cars were not introduced, as in England, in order to compete with tramway lines running parallel to the railways and taking away some of their local traffic; but they were started in order to improve, at a moderate expense, local communications and to give a service at certain stations at which express trains do not stop.

The notion of utilizing automotor cars in order to satisfy certain desires of the

public by instituting cheap and provisional services of an experimental kind, has found no application, according to the information received, except in a few very exceptional cases. On the other hand, it was sometimes found necessary on the Orleans Railway, and rather frequently on the Italian State Railway, to replace automotor cars by locomotives, the rush of passengers to the supplementary trains having increased beyond what was expected.

In Germany automotor cars are rather frequently replaced by locomotives on holidays, either because there is a rush of passengers, or in order to give the employees a rest and clean the cars and attend to their upkeep. Certain runs, on which work men or school pupils are carried, are not made on Sundays.

Stabling of automotor cars. — The automotor cars are everywhere housed in the locomotive sheds, except at some places, where the absence of such installations has made it necessary to put up a simple shed; the accumulator car of the Saxon State Railway stops during the night in Dresden station. The automotor cars are repaired at the locomotive or the wagon shops, according to the class of work required.

The staff operating the automotor cars and looking after their upkeep is always the same as that utilized for the locomotives; some administrations however try to specialize it as much as possible.

III. — Technical and economical results.

Distance run without taking in supplies. — From the point of view of the utilization of automotor cars, given the nature of the service to be carried out, the distance which can be run without taking in supplies is an important factor; but difficulties of a constructive order generally impose a rather short limit to this distance in the case of steam cars and of accumulator cars. Another unfavourable condition is the small efficiency of the boilers and steam engines used, which leads to rather high consumptions.

The steam cars about which we have received information can run a distance of from 150 to 250 kilometres (93 to 155 miles) (according to type, load hauled and profile of the line) without taking in supplies. They can run from 20 to 55 kilometres (12·4 to 34 miles) without taking in water.

The distance which can be run without recharging the batteries is 30 to 40 kilometres (18·6 to 25 miles) in the case of the Bavarian accumulator cars, to 90 kilometres (56 miles) in that of the Saxon State cars, and 100 to 150 kilometres (62 to 93 miles) in that of the Belgian State cars.

The petrol cars are in this respect specially favoured, because for an equal weight of supplies, they can run much further than other cars (the distance amounts to 280 kilometres [174 miles] in the case of the Daimler cars), and the supplies of petrol can be taken, while stopping, very quickly and easily.

In the case of steam cars having boilers heated with coal, the maximum run that can be made without stop is limited, moreover, by the state of the fire, after running about a hundred kilometres (62 miles), even under the most favourable conditions; while cars of other systems are not limited in this respect.

The steam cars are generally supplied with water by the same appliances as are used for the locomotives. In some cases however the construction of the car makes it necessary to put up special water-cranes.

Tractive power, speed. — The most characteristic information we have received concerning the busiest services, is as follows :

The Ganz steam cars of the Bavarian State Railway and of the Austrian Southern Railway attain the speed of 60 kilometres (37·3 miles) per hour on the flat, without trailers, and of 35 to 40 kilometres (21·7 to 25 miles) per hour with one or two trailers (12 to 25 tons [11·8 to 24·6 English tons]). On long ascending gradients of 10 per mil the speed was 25 to 30 kilometres (15·5 to 18·6 miles) per hour without trailers and 20 kilometres (12·4 miles) per hour with one trailer.

The Serpollet car of the Austrian State Railway runs at 40 kilometres (24·8 miles) per hour on the flat, and at 18 kilometres (11·2 miles) per hour on an ascending gradient of 14 per mil; it runs as a rule without trailers.

The Komareck cars (series 1001-1002) of the Austrian State Railway attain a maximum speed of 50 kilometres (31 miles) per hour, and series 1001 attains 60 kilometres (37·3 miles) per hour; on an uphill gradient of 22 per mil they haul 20 tons (19·7 English tons) at 18 kilometres (11·2 miles) per hour.

In the case of the Purrey cars with two axles, the administration of the Italian State Railway finds that 80 horse-power are given normally, and 100 horse-power exceptionally, when hauling one and two trailers respectively, at speeds of 30 to 35 kilometres (18·6 to 21·7 miles) per hour, up long ascending gradients of 15 per mil.

The Purrey cars with three axles on the Orleans Railway attain the very remarkable inclusive speed of 67 kilometres (41·6 miles) per hour normally; and as they often make up lost time they attain 80 kilometres (49·7 miles) per hour on the flat.

The Wurtemberg State Railway states that the Serpollet cars run at a speed of 40 kilometres (24·8 miles) per hour on the flat and at a speed of 15 kilometres (9·3 miles) per hour on an ascending gradient of 10 per mil with a trailer; the maximum speed without trailer is 60 kilometres (37·3 miles) per hour. The cars with Kittel boiler, belonging to the same railway, attain the same maximum speeds and give about 80 horse-power, which corresponds to a load of 30 tons (29·5 English tons) hauled on the flat at the speed of 55 kilometres (34·2 miles) per hour and up a 10 per mil gradient at the speed of 25 kilometres (15·5 miles) per hour.

The four-axle steam cars of the Bavarian State Railway usually run at 75 kilometres (46·6 miles) per hour on the flat, even when hauling 40 tons (39·4 English tons). Up gradients of 10 per mil, they attain speeds of 55 to 60 kilometres (34·2 to

37·3 miles) per hour without trailers, and of 40 kilometres (24·8 miles) per hour when hauling 40 tons (39·4 English tons). The power developed is about 160 to 200 horsepower.

The four-axle cars of the Italian State Railway haul on the flat 45 to 60 tons (44·3 to 59 English tons) at 50 kilometres (31 miles) per hour, and up 15 per mil gradients they haul 20 to 30 tons (19·7 to 29·5 English tons) at 30 kilometres (18·6 miles) per hour; the maximum speed authorized is 60 kilometres (37·3 miles) per hour, but 70 kilometres (43·5 miles) per hour are easily attained.

The motor luggage-vans, whose maximum authorized speed is also 60 kilometres (30·7 miles) per hour, can haul 30 tons (29·5 English tons) up gradients of 18 per mil at 30 kilometres (18·6 miles) per hour, or 40 tons (39·4 English tons) up gradients of 10 per mil at 40 kilometres (24 8 miles) per hour.

The Daimler petrol cars run at the maximum speed of 40 kilometres (24·8 miles) per hour on the flat, of 20 kilometres (12·4 miles) per hour up 10 per mil gradients, of 14 to 18 kilometres (8·7 to 11·2 miles) per hour up gradients of up to 16·7 per mil; in all cases without trailers.

Remarks concerning the regularity and the flexibility of service. — The administrations who have used or tried automotor cars of small size and very limited power complain particularly of the want of flexibility of these cars with regard to the needs of the service. The administrations of the Saxon State Railway and the Swiss Federal Railway both express this view. Similar opinions have been expressed by the Wurtemberg State Railway as regards its Daimler and Serpollet cars only, the Paris-Lyons-Mediterranean Railway as regards its Serpollet cars, and the Italian State Railway as regards its Purrey cars with two axles. Several of these administrations also remark that there is a certain difficulty in running a service which is perfectly regular.

This want of flexibility is also admitted by those railways which use medium-power cars, for instance the Bavarian State Railway and the French State Railway.

Several administrations remark that the flexibility required for the varying needs of the service is necessarily limited by the limited dimensions of the boilers or engines of the automotor cars, and consequently by the small reserve of energy available. It is however observed that it is possible to obtain fairly regular running, and even to make up for lost time, by leaving a sufficient margin when drawing up the time-tables; in many cases this results in reducing the inclusive speed.

The administration of the Wurtemberg State Railway informs us that its last automotor cars, with Kittel boilers, give satisfactory results when used for local services, and that irregularities in the service are neither important nor more frequent than with the ordinary locomotives. The Paris-Lyons-Mediterranean Railway makes a similar statement about its Purrey cars, particularly as regards the more recent ones with three axles, providing they are not overloaded.

Remarks about maintenance. — The majority of the administrations which use or have used motors or boilers of special type state that the maintenance, in consequence of the special design and the complications of the parts, is more troublesome than in the case of locomotives.

The administration of the Austrian State Railway, however, states that the upkeep of the Komareck boilers, in the district in which the quality of the water is not bad, gives rise to neither special difficulty nor considerable expense. The same information is given by the Italian State Railway, in so far as any conclusion can be drawn from the results obtained with the first boilers of this type, which have only been in use for about one year.

The Purrey cars, which have given some trouble on the French State Railway, give good results on the Orleans Railway and on the Paris-Lyons-Mediterranean Railway, if kept properly cleaned; the same can be said of the cars of the Italian State Railway, which however are not running at the present moment, as they no longer were able to cope with the increased traffic.

According to the administration of the Wurtemberg State Railway, the vertical Kittel boilers, apart from some small leaks at the tube-plates which occurred at the start, and which were caused by the bad quality of the water and by want of care, do not require more upkeep than those of ordinary locomotives.

The vertical boilers of the motor luggage-vans of the Italian State Railway showed more leaks and a more costly upkeep, owing to their somewhat forced utilization in certain services for which they were formerly used. The modified boilers (fig. 11 and 12), which have now been tried a short time, appear to behave better.

The upkeep of horizontal boilers, of the locomotive type, which are used on some of the cars of the Bavarian State, the Belgian State, the French State (luggage-van locomotives) and the Italian State railways, do not call for any special remark as compared with the boilers of ordinary locomotives. It has however been remarked that the greater lightness of the mechanism often means greater care and more costly maintenance being necessary.

In the case of automotor cars having a motor truck separate from the main frame, the Orleans, the Paris-Lyons-Mediterranean and the Italian State railways have one or two spare trucks, so as to facilitate maintenance and reduce the immobilization of the cars. The administration of the Bavarian State Railway also provides for this.

The stabling of the automotor cars in the sheds used for the locomotives does not seem to have given any special trouble or difficulty as regards deterioration of the upholstering and the accessories, and as regards keeping it in a good state of cleanliness.

Frequency of laying up and replacement owing to a rush of passengers. — Locomotives are substituted for the automotor cars regularly every Sunday and holiday on some of the German lines. On the Swiss Federal Railway, this substitution is even regular on market days.

The immobilization of the automotor cars owing to this substitution of locomotives on holidays and market days is stated by the Paris-Lyons-Mediterranean Railway to be *rather frequent;* on the Orleans Railway, this immobilization extends to from 5 to 20 per cent of all the automotor car trains. On the Italian State Railway, the automotor cars and the motor luggage-vans have had to be withdrawn from certain services, in which the periodical increase of the passengers on certain weekdays or at certain seasons made it necessary either to work the motors excessively or to replace them too frequently by locomotives. This inconvenience is however considerably reduced by organizing the services so that the automotor cars and motor luggage-vans are only used in the cases they suit best.

It would have been desirable to give more complete particulars regarding the average frequency of the immobilizations of automotor cars in the ordinary service, but we have not received more detailed information.

Reduction in the number of classes. — One measure which may be considered peculiarly effective in facilitating the formation of small train units while making it possible to carry a fairly considerable number of passengers, is the adoption of one single class for services of an entirely local character.

This system has been largely applied by the administration of the Wurtemberg State Railway, which finds it very satisfactory from the point of view of the simplification of the service.

The reduction from three to two classes has been adopted by most of the administrations who have local trains hauled by automotor cars.

Influence of the automotor-car journeys intercalated on the regularity of running of the other trains. — On lines and at stations with much traffic where the number of trains has been considerably increased by intercalating automotor-car journeys between the existing trains, it was to be feared that certain inconveniences might arise in connexion with the occupation of the stations on the regularity of running of the trains. The administration of the Saxon State Railway at first suffered from such inconveniences, but they have been reduced since. All the other administrations answered this question in the negative.

Consumption of fuel. — The data received, which bear a relation to the weight and the speed of the trains, particulars of which are given in the preceding table, are given in table III below.

Cost per kilometre. — The information received on this point is very limited, as was to be expected, considering the experimental character of the use of the automotor cars on some of the railways where the cars at present used are of recent construction and where the programme of their utilization has not yet been definitely settled.

Table III.

Railway.	Type of automotor car.	Mean total weight of train, automotor car included (in tons English tons).	Fuel used.	Gross consumption in kilograms per kilometre (in lb. per mile) (lighting up, etc., included).	*Remarks.*
Saxon State Railway.	Petrol, Daimler	20 (19·7)	Petrol, alcohol.	0·580 (2·058) (alcohol) (1)	(1) And in addition 0·725 kilogram (1·601b.) of petrol for lighting up.
Wurtemberg State Railway	—	25 (24·6)	Petrol.	0·330 (1·171)	
Austrian State Railway.	—	16 (15·7)	Petrol.	0·290 (1·032)	
Swiss Federal Railway	—	17 (16·7)	Petrol.	0·321 (1·139)	
Bavarian State Railway.	Steam, Ganz	17 (16·7)	Coke.	3.600 + 0.300 (2) (12·773 + 1·064)	(2) Charcoal.
Austrian Southern Railway	—	32 (31·4)	Coal.	4·530 (16·072) (3)	(3) Calorific power, 5,000 to 6,000 calories (9,000 to 10,800 British thermal units per lb.).
Saxon State Railway.	— Serpollet.	...	Coke.	2·360 (8·373) (4)	(4) And in addition 0·450 kilogram (0·991b.) for lighting up. Withdrawn from service.
Wurtemberg State Railway	—	...	Briquettes.	2·680 (9·508)	
Paris-Lyons-Mediterranean Railway	—	...	Petroleum.	1·200 (4·258) (5)	(5) At present withdrawn from service.
French State Railway	— Purrey, with 2 axles.	(*)	Coke.	5·000 (17·740)	
Paris-Orleans Railway	— — 3 —	...	Coke.	8·600 (30·512) (6)	(6) High speed, see table II.
Paris-Lyons-Mediterranean Railway	— — 2 —	50 (49·2)	Coke.	5·150 (18·272)	
Italian State Railway	— — 2 —	50 (49·2)	Coke.	5·100 (18·094)	
Wurtemberg State Railway	— Kittel	(*)	Coal.	2·680 (9·508)	
Austrian State Railway.	— Komareck	(*)	Coal (7).	8·400 (29·803) (7)	(7) Bohemian coal. Coefficient of evaporation, 4 to 5.
Belgian State Railway	— Belpaire	(*)	Coal (8).	6·500 (23·062)	(8) Semi-fat.
Bavarian State Railway	with 4 axles.	(*)	Coal.	8·000 (28·383) (9) 9·500 (33·705) (10)	(9) Ruhr coal. (10) Bohemian coal.
Italian State Railway	— with 4 axles series 85.	60 (59·1)	Coal.	6·400 (22·707)	
— —	— with 4 axles, series 86	67 (65·9)	Coal.	6·400 (22·707)	
— — —	— motor luggage-van, series 60	87 (85·6)	Coal.	8·400 (29·803)	
	Small locomotives :				
Bavarian State Railway	Steam with 2 axles.	...	Coal.	4·000 to 7·000 (9) (14·192 to 24·836) 5·000 to 8.500 (10) (17·740 to 30·157)	
French State Railway	Steam, luggage-van locomotives	...	Coal.	7·000 (24·836)	

(*) See table II.

The administration of the Bavarian State Railway, not being as yet in a position to determine the cost of staff and upkeep, has only given the cost of the materials used, which is as follows :

—	Ganz cars with two axles.		Cars with four axles.	
	Franc.	(Pence.)	Franc.	(Pence).
Fuel, per kilometre (per mile).	0·144	(2·225)	0·198	(3·059)
Lubricant, per kilometre (per mile)	0·013	(0.201)	0·017	(0.263)
Other materials, per kilometre (per mile)	0·003	(0·046)	0·005	(0·077)
Total for materials, per kilometre (per mile). . .	0·160	(2.472)	0·220	(3.399)

The Austrian Southern Railway gives, for its Ganz cars, a total expenditure (materials, staff, upkeep) of 0·298 franc per kilometre (4·604*d*. per mile), while it estimates at 0·290 franc per kilometre (4·480*d*. per mile) the cost of traction in the case of the tank locomotives used for similar services.

The total cost of traction per kilometre amounts, according to the administration of the Saxon State Railway, to 0·620 franc (9·579*d*. per mile) for the Daimler cars, to 0·550 franc (8·497*d*. per mile) for the Serpollet cars, and to 0·400 franc (6·180*d*. per mile) for the tank locomotives, of suitable type, hauling one carriage.

According to information supplied by the administration of the Wurtemberg State Railway, the same costs per kilometre on this railway amount to :

—	Daimler car.		Steam car, Serpollet and Kittel system.	
	Franc.	(Pence.)	Franc.	(Pence.)
Fuel, per kilometre (per mile)	0·115	(1·777)	0·070	(1·081)
Lubricant, per kilometre (per mile).	0·013	(0·201)	0·004	(0·062)
Traction staff, per kilometre (per mile)	0·057	(0·881)	0·075	(1·159)
Upkeep, per kilometre (per mile)	0·047	(0·726)	0·060	(0·927)
Total. . .	0·232	(3·585)	0·211	(3·260)

The cost of various items (lighting, steaming, water, etc.) is not given.

Finally, the data, per kilometre, deduced from the information supplied by the Austrian State Railway are :

—	Daimler cars.	Serpollet cars.	Komareck cars.	Locomotives, Series 86 and 185.
	Franc. (Pence.)	Franc. (Pence.)	Franc. (Pence.)	Franc. (Pence.)
Fuel, per kilometre (per mile) . . .	0 084 (1·298)	0·062 (0·958)	0·069 (1·066)	0·125 (1·931)
Lubricant, per kilometre (per mile) . .	0·024 (0·371)	0·020 (0·309)	0·019 (0·294)	0·005 (0·077)
Water, per kilometre (per mile). . .	...	0·005 (0.077)	0·005 (0·077)	0·004 (0·062)
Cleaning materials, per kilom. (per mile)	0·005 (0·077)	0·005 (0·077)	0·008 (0·124)	0·007 (0·108)
Traction staff, per kilometre (per mile).	0·109 (1·684)	0·108 (1·669)	0·140 (2·163)	0·177 (2·735)
Upkeep, per kilometre (per mile) . .	0·094 (1·452)	0·109 (1·688)	0·090 (1·390)	0·044 (0 680)
Total. . .	0·316 (4·882)	0·309 (4·774)	0·331 (5·114)	0·362 (5·593)

The figures giving the cost prices are not complete; these however vary within very wide limits, and the prices cannot all be compared.

An interesting deduction can however be drawn from the comparison between the cost prices of automotor cars and of equivalent locomotives *belonging to one and the same administration.*

We have the following particulars available :

Bavarian State Railway. — The steam cars with four axles cost 59,000 francs (£2,360), while the small locomotives cost about 36,000 francs (£1,440).

Austrian State Railway. — The Komareck cars cost 38,000 francs (£1,520) and 54,000 francs (£2,160), according to series, while the small locomotives of the two series cost 23,000 and 29,500 francs (£920 and £1,180).

We see that the difference between the two prices represents the cost price of an ordinary carriage with a capacity similar to that of the autocar.

On the other hand, as we have already seen, the annual mileage of the locomotives can more easily attain high figures.

It follows from this that the cost per kilometre for interest and renewal of the stock does not give less favourable figures in the case of locomotives than in that of automotor cars.

CONCLUSIONS.

Automotor cars, examples of which are already to be found when railways first began (1), were not used, until about 1895, except quite exceptionally and for applications of short duration. Their use has assumed a certain development since, with a view to satisfying, economically, the continually-growing demand for frequent communications, either on secondary lines, or at small stations on main lines.

This resumption of the application of automotor cars has given rise to a considerable number of new types of cars, specially designed with a view to the new requirements, and profiting by the technical progress which has been realized.

A comparatively large number of cars of several of these new types are at present in regular service on different lines on the continent of Europe; others are utilized for services which are still of an experimental character. Nevertheless the administrations who have answered our list of questions agree in informing us that they have at present no automotor car under construction, and do not for the moment foresee any further extension of the automotor-car services.

The economic advantages which may be expected from the use of automotor cars consist essentially in the reduction of the number of employees and in the formation of small train units which represent a reduced capital outlay and consequently reduced charges for interest and renewal; this result is only attained by sacrificing part of the flexibility locomotives usually have.

But this flexibility, on the advantages of which it is unnecessary to dwell, may sometimes become an obstacle to the realization of a very economic service, given that in practice the composition of the train, increased for exceptional requirements, can easily be conserved as normal, although a lower *average* utilization of the seats results.

The necessarily limited power which characterizes automotor cars is, on the contrary, a guarantee that the reduced size fixed for the trains is really adhered to, and this ensures the realization of the economies it was proposed to effect. But these economies cannot be realized except under condition of having traffic which is *nearly always equally* large; for in fact if it was frequently necessary to replace the automotor car by a locomotive, the mean annual utilization of the automotor cars would become very low; and the charges for interest and, in part, for amortization, would be nearly doubled.

---

(1) The oldest are the Adams cars, with boiler of locomotive type, used between London and Norwich in 1849, and others, with vertical boiler, which were utilized between Bristol and Exeter. Next came the Fairlie cars, with horizontal boiler, and the Fairlie and Samuel cars, with vertical boilers, in 1868. We next find in Switzerland the Brunner steam omnibus, used on the Lausanne-Echallens line in 1876; and in 1877 the first Belpaire cars on the Belgian State Railway and on the lines of the old railway company of upper Italy. (For further details, see Guillery, *op. cit.*)

It must also be noted that the annual mileage of automotor cars, even under favourable conditions, cannot be compared with that which can be obtained with ordinary carriages. This mileage depends, in fact, on the periods of immobilization resulting from the repairs of the mechanical part. It follows that the immobilization of the carriage part is increased by the fact of its connexion with the motor, and this represents a percentage (for interest and amortization) on the value of the carriage part, higher than in the case of ordinary carriages. This disadvantage can be eliminated by the use of separate motor trucks.

The reduction of the staff required for the service cannot, as mentioned above, be realized under all conditions of the service, of the line, etc., or in the case of all types of automotor cars, chiefly owing to the care required in driving the engine.

The whole of the information received and of the particulars discussed, leads to the following conclusions :

1° Automotor cars can be used in certain cases for economic services, in order to facilitate local communication at a moderate outlay, provided that the traffic conditions lend themselves to the organization of frequent trains, carrying a regular traffic or at least one which only varies rarely and but little, that the line is an easy one and that the goods traffic can be carried conveniently and completely on separate trains;

2° The power of the motors of the automotor cars should present a certain margin beyond the ordinary work, so that it is possible to cope with variations of the traffic within certain ascertained limits;

3° It would be desirable to make it possible to utilize the car independently of the motor by having either separate motor trucks, or some other device making it possible to remove and replace the mechanical part easily.

4° From the point of view of economy of staff, that is to say having only one traction agent, accumulator or petrol cars seem the most suitable. The types used by the administrations who have given us information represent units of too low a power. It would be desirable that investigations should be made in order to increase this power suitably (1), and to ensure easy and inexpensive maintenance.

5° As regards steam cars, it would be desirable to reduce to a minimum the care required for the boiler and in particular to improve the semi-automatic feeding of the grate or to improve the methods of using liquid fuel.

6° It would be desirable to recommend the investigation of small locomotives able to replace automotor cars, with the advantage of greater independence. The luggage-van locomotives, or the motor luggage-vans, represent an intermediate solution, which it seems can be suitably applied in certain cases.

---

(1) This line has been adopted on the Prussian State Railway in the case of accumulator cars, and on some of the United States lines, in that of petrol cars.

APPENDIX I.

Detailed list of questions relating to question XII.

N.-B. — *The reporter begs administrations who have no automotor-cars in service at present but who have experimented with them in the past to be kind enough to reply to the questions put, explaining the reasons for having given up the system.*

Similarly he hopes administrations who have motors on order will supply detailed information as regards the pattern selected and the purposes they are designed to serve in operation.

LIST OF QUESTIONS.

I. — Description of railway automotor cars.

A. — What are the various types of automotor-cars, or motor luggage-vans, which you have in use on your Railway?

B. — Will you kindly supply the following data and particulars :

1. Kind of motor :

a) If driven by steam.
b) If by explosion of oil or gas with merely a mechanical transmission of motion.
c) If by explosion with transmission and electric driving gear.
d) If electric with accumulators.

Note. — The interrogatory does not take into account the electric automotors taking their current from outside.

2. Design of the automotor-car (elevation and plan), preferably to the scale of $^3/_4$ inch to 1 foot.

Please also show on plan :

Driving axles;
Coupled axles;
Gauge of track;
Section of rails;
Distances from centre to centre of the axles and of bogies;
Diameters of wheels respectively;
Length over buffers;
Length over body;
Width over body;
Width and the inner height of compartments;
Maximum height from rail.

3. General design, with sections, of the motor, of the boiler (if any), and accessories, preferably to the scale of $^3/_4$ inch to 1 foot.

It would be advisable to have, apart from above, the most characteristic details of construction.

For automotors consisting of an independent engine, or else of an almost independent motor-truck, and of a car fastened to said engine, or else carried on one end by the underframe and on the other end by an axle or an ordinary bogie, please show how the car is joined to the engine.

4. Weight of the automotor when empty.

Weight of the engine alone, where it constitutes a separate underframe.

Weight when at work, with its full outfit (water, fuel, etc.); but without passengers or luggage.

How is said weight apportioned over each pair of wheels.

In the event of the weight per pair of wheels being limited by the state of the line and the bridges you are asked to say :

The maximum weight of the load allowed on the rails.

The weight of the rails per yard.

The length of the rails, and the number of sleepers for each rail.

5. You are also asked to state what would be the approximate weight, when empty, of an ordinary car or luggage-van of your normal type, the most similar from the point of view of comfort, strength, stability, etc., to the automotor-car having the same capacity for passengers and luggage.

6. What are the classes and number of seats available for each class ?

Limit of weight, or maximum capacity of the luggage-compartment; and (if there is one), of the compartment for the mails.

7. Brake-gear : Screw-brakes, lever-brakes, steam brakes, etc., continuous brake (of what system?).

Wanted to know, for each brake gear if it acts on all the wheels on the automotor-cars, or on part of them only.

8. System of heating.

System of lighting : for the car; for the driver's cab, for the outside lamps, at front and at tail end.

9. Is the automotor-car provided with buffing gear of the normal type of your railway system, or have you adopted gear of a special type in view of an exclusive service with or without trailing cars specially built? In the second case you are asked to supply a sketch.

10. For motor-cars or motor luggage-vans *with steam motors* you are asked to state :

a) the type of boiler, with particulars of details for the special systems;

b) the grate area; the number, length, and inner diameter of the tubes; the heating surface of the fire-box; the heating surface of the tubes, of the tube plates, of the fire-box plates (*for boilers of locomotive type, and for vertical boilers with smoke tubes*).

Corresponding data for water-tube boilers or special types.

If making use of super-heating apparatus you are asked to give separately the value of the heating surface for the production of saturated steam, and of the surface of super-heating and to give the average and maximum temperature of the super-heated steam.

c) The number and type of feeding apparatus (injectors or pumps), of safety valves, blower; sizes and system of blast pipe (fixed or variable?);

d) normal pressure;

e) the kind of coal used : lumps, patent fuel, small, or coke.

In case of making use of a charging cone for the mechanical and continuous feeding of the fire-box, please give details;

in case of using liquid fuel, you are asked to send the scheme of the combustion apparatus, and to name the kind of liquid fuel used : rough mineral oils, residues of distillation, or other matters.

*

Kindly say :

1° if the liquid fuel is used exclusively during the journey or mixed in combustion with coal or coke;

2° if, in the latter case, you use exclusively at times, the liquid fuel, or the coal, according to the changes in the cost price of the two qualities of the above-mentioned fuels.

f) the data relating to the mechanism; simple or double expansion? Number of cylinders, diameter, length of stroke, type of distributors; system of distribution, return of transmission in case where a chain, or a cog-wheel gearing return is made use of, etc., particulars of the details of the motion and of the construction of the details, lubrication etc., which may offer particular interest.

11. When explosion automotors are made use of, either with electrical driving-gear or accumulator electric system, kindly send detailed description of the system, with characteristics of the automotor and the data relating to the methods of transmission.

12. Location of the cab or cabs, for the driver. Is there one cab only at one of the ends? with what arrangement for travelling backwards, if such is allowed? or are there two similar cabs with identical or other outfit, one at each end?

For automotor-cars having at one end a complete engine, and at the other an auxiliary cab occupied by an acting motorman during the travelling backwards kindly give the outfit of the auxiliary cab, and the means of intercommunication with the cab of the engine; of electric ringing, whistle (steam or compressed air); of working of the regulator (closed only, or closed and open?); of the working of the continuous brake; of the screw brake (acting on all the wheels of the automotor-car); etc.

13. Have you thought of adopting for the local trains or light trains, small locomotives specially designed in view of a very economical service, instead of the automotor-cars?

In the affirmative, kindly forward the scheme, the data characteristic of the boiler and the mechanism, the weight when empty, the full weight when at work and its load per pair of wheels.

14. If you have no small locomotives specially designed for services similar to those which are worked by your automotor-cars, please send the particulars asked for in question No. 13, for passenger locomotive-tenders of the lightest type you have in service.

II. — Organization of the service. Mode of working.

1. For each of your types of motor-cars, you are asked to state if you employ them exclusively isolated, or with trailing cars.

In the second case, is there intercommunication between the automotor-car and the car following, and between one and the other of the trailing cars?

Do you make use exclusively of the plant with continuous brake or not?

2. Please say for each of your automotor-car types (including the automotor luggage-vans, postal wagons, motors, etc., if the handling is entrusted to two traction agents or to only one.

Show the number of working agents whom you employ, over and above the said traction agents :

a) for the automotor-cars working alone,

b) for the automotor-car towing one or several cars.

In the second case, does the number of agents depend on the number of cars, on the declivities of the line, on the existence or otherwise of passages for intercommunication, on the working or otherwise of the brake?

3. For automotor-cars that have one single cab for the driver or motorman at only one end, you are asked to say if, at the end of the journey you always turn the automotor-car on the turntable.

In the contrary case, what is the maximum speed which you allow when the automotor-car travels with the driver's cab at the trailing and leading ends respectively.

In view of avoiding shunting at the end of the journey, for the local to and fro services, do you allow the circulation of automotor-cars pushing one or several cars. What is, in this case, the maximum speed allowed?

If more than one car is attached to the motor-car do you push any in front; if so how many do you allow, or do you always attach the additional cars on behind so as to draw them.

4. For the automotor-cars having a complete engine at one end and an auxiliary cab with ringing, whistle, brake, etc., at the other end, and handled by one motorman and one assistant motorman (driver and stoker), does the driver, in the case of travelling backwards, ake his post at the front, that is to say, in the auxiliary cab, and does the stoker remain in the engine cab, or *vice versa?*

If, on the contrary, you employ for these automotor-cars only one motorman, does the said man, while travelling backwards remain in the engine cab, the cab at the front end being occupied by the train guard or by a brakesman duly authorised?

5. In the case of small locomotives, referred to in question 1-13, have you adopted the system of entrusting the handling to one man only?

Do you use continuous brakes upon the motor-cars and also where they haul trailer-cars, and have you intercommunication with the first car hauled or all cars hauled or pushed.

Do you use liquid fuel or any arrangement for the continuous automatic feeding of the grate with coal?

6. Please supply profile of the lines or sections of lines worked by the automotor-cars, showing the distances between the stations, the differences in altitude, the maximum gradient and their length, the longest gradients and their development, the minimum radius of the curves.

7. Enumerate the services daily performed on your system by the automotor-cars, showing the types of automotor-cars respectively used, the stations at the extreme ends and mileage corresponding to each run, the total running per day for each of your types of your automotor-cars and the general total.

Are any of those services divided into two stages, worked by two different automotor-cars, on account of the length of the journey? Please also give the maximum daily working for automotor-cars of your various types; or better still give if possible, the rotation of the automotor-cars in a graphic form.

8. Average weight when empty and when at work, number of seats available for each class; number of axles of the cars usually hauled or pushed by the automotor-cars.

9. For every one of the journeys worked by your automotor-cars (See No. 7), kindly show :

a) The average and maximum number of the hauling cars and the total weight corresponding thereto (inclusive of travellers, luggage, etc.)

b) The time-table, showing stoppages, and times of departure and arrival.

10. For each type of automotor-cars on your system, you are asked to state : the number actually in existence; the date of building the oldest and the last; the number of units effectively employed in the daily service; the average number of units stopped for washings, repairs, eventual substitutions; the annual mileage run per motor-car.

11. For the small locomotives referred to in question I-13, if you have such, you are asked to reply to question 6 to 10, as above, inasmuch as this may be of interest, with regard to comparison with the automotor-cars.

12. As regards the conditions for carrying passengers, do you inform the public what are the runs provided for by the time-table, and worked by means of automotor-cars?

Are they considered as trains with a *limited number of seats?*

In the contrary case, if there comes about an extraordinary rush of passengers, do you start a supplementary train, hauled either by another automotor-car or by a locomotive, or do you merely start a locomotive with a larger number of cars instead of the automotor-cars?

Are the runs provided by automotor-cars, submitted to fixed times with other trains, or have they an exclusive character of local service, independently of any coincidence.

13. Is your programme for the use of automotor-cars for secondary lines limited to various supplementary runs sandwiched between the abready existing trains hauled by the locomotives?

Hase you made use of, or do you think of using the automotor-cars, *for the complete service of passengers* on some branch, or some short line? Have you been obliged, in that case, to create goods trains hauled by the locomotives, whereas previously you had only mixed trains? How have you managed for the carrying of cattle and express goods?

14. Does your working programme include an extended use of automotor-cars on the principal lines? In the affirmative, what would be essentially your purpose? Fight the competition of the tramways, or other means of communications at short distances? Or rather, to improve at a moderate expense, certain communications having a local or outskirt character? Have you perhaps thought of making use of the automotor-cars to create on several sections of the long lines, journeys with stops at all the stations, a little before and directly after the passing of the long-run express trains, for the purpose of improving the communications of the less important centres without increasing the number of stoppages of the express trains?

15. Have you also thought of utilising the automotor-cars, to set up, at a moderate expense, temporary communications by way of trial, in order to ascertain the quantity of passengers, with a view to converting them, after a given time of experiment, and in case of good results, into passenger trains, hauled by locomotives and to suppress them, if otherwise? Have you any instances?

16. Have you preferably allotted automotor-cars to sundry local journeys that do not occur on Sundays and holidays? Do you avail yourself of these interruptions for washing and upkeep, with a view of working the system with a smaller number of reserve automotor-cars?

17. Are your automotor-cars stored and kept up in the same sheds as the locomotives? Or have you organised a service of separate sheds? Are these sheds worked by the same staff which attends to the service of the locomotives, or have you specialised staff?

III. — Technical and economical results.

1. For each of your type of automotor-cars, please say the maximum distances which you can practically run in regular service, bearing in mind the handling of the firing, the supplies of water and fuel, etc.

2. For taking in the water at the intermediary stations, do you take a longer time than with the locomotives, on account of the less convenient arrangements? Have you had to fall back upon special fixings (hydrants, etc.), to make these easier, or do you make use of the same hydraulic cranes fitted up for the use of the locomotives?

3. Please give some information concerning the most difficult performances that you have been enabled to carry out with automotor-cars, from the point of view of effort of traction, the working of the boilers, and the speed (hauled load, average and maximum gradient and its length, maximum journey without stops, average *effective speed in full work realised* without excessive effort on said inclines, etc.).

Maximum speed realised on the level under good conditions of stability and with regular working of the automotor.

4. What remarks have you to make on the results obtained during regular working from the point of view of power and above all, the smoothness of working, bearing in mind the requirements of the service?

As regards the load and the time-table referred to in question II, have you not found any difficulty in the regularity of the travelling? Can you even make up for loss of time?

5. Have you found no difficulties in the upkeep : *a*) of the boiler; *b*) of the automotor, owing to its special and generally more delicate construction than that of the locomotives?

With particular reference to the boiler, have you not had trouble because of the quality of the water used?

In order to facilitate the up-keep of the engines, have you spare motor-trucks, in the case of the automotor-cars, with the motor-truck separable from the main under-frame.

6. Being given the necessity of storing and upkeeping the motor-cars in the locomotive sheds and the connection of the cars with the mechanical part, have you not had any trouble brought about by the deterioration of the car, particularly of the upholstering and the accessories, and by the difficulties of keeping it in a good state of cleanliness.

Have you not had trouble by the depots being encumbered on account of the length of the automotor-cars?

7. Have you often been compelled to put aside the automotor-cars, replacing them by locomotives on occasions of a great rush of passengers, recurrently (market-days, holidays, etc.); again at certain stated seasons (bathing, holidays, etc.), or yet again accidentally?

8. Have you found any advantage in reducing the classes to one only, even for trailing-cars?

9. Has the number of automotor-car journeys sandwiched between the already existing trains given rise to obstructions, to difficulties in the operations at the station, to delays to the principal trains, on the lines having a great number of express-trains and goods trains.

10. Average consumption of fuel per mile, including consumption for lighting and stoppages.

11. Average cost per mile for greasing, lighting, water, traction-staff, cleaning, upkeep of the mechanical part (including heavy and light repairs), and the upkeep of the car.

12. Data similar to those asked for by the questions number 10 and 11, for the small locomotives dealt with in question I-13, or for the ordinary tender-locomotives dealt with in question I-14.

13. Average price of the automotor-cars of your various types, in comparison with the price of the locomotives, dealt with in the fore-going question.

14. Have you other automotor-cars building? of what type? do you intend extending the use of them?

APPENDIX II.

Principal data referring to the automotor cars and small tank locomotives used for similar local services.

(1) Each cylinder contains two working pistons placed next each other, each acting on one axle of the locomotive; the two axles are coupled.
(2) The grate is fed semi-automatically by a charging-cone filled from the roof of the cab.
(3) Each axle of the car has a 48-horse-power motor. The capacity of the accumulator battery is 160 ampere-hours.
(4) Twenty of them under construction.
(5) The automotor is formed by the connexion of two vehicles, each with two independent axles.
(6) Each axle has a motor of 27 horse-power. The capacity of the accumulator battery is 430 ampere-hours.
(7) The Serpollet car is now not used.

(14) At present two other types of boilers are being tried for these motor luggage-vans; one vertical with smoke tubes, but with enlarged barrel, the dimensions being nearly the same as in the normal type; the other is a horizontal boiler of the locomotive type, placed crosswise, with very short smoke tubes, a grate area of 1 square metre (10·764 square feet), and a heating surface of 52·25 square metres (562·435 square feet) (Serve tubes).

(15) Without the boiler room.

Remarks : *A*. The Baden State Railway has tried, as an experiment, a Serpollet steam car with two axles, similar to those of the Wurtemberg State Railway, and an electric accumulator car. At present these cars are not used any more. *B*. The automotor cars with internal-combustion motors considered in the table all have mechanical transmissions. No information has reached us from any administrations owning cars with internal-combustion motors and electric transmission (benzo-electric, Weitzer type, etc.) except the Belgian National Suburban, which has recently decided to try a new type of car on the "Automixed" system based on the combined use of petrol or poor-gas motor, a dynamo, an accumulator battery and electric motors. *C*. The Swiss Federal Railway formerly had a Serpollet car in use, subsequently withdrawn from service.

REPORT N° 3

(Great Britain and colonies)

By Mr. T. Hurry RICHES,

LOCOMOTIVE CARRIAGE AND WAGON SUPERINTENDENT TAFF VALE RAILWAY.

From enquiries made of the various railway companies in Great Britain and her Colonies, it is found that on the twenty-one railways, named below, motor cars have been experimented with and put into ordinary traffic.

It will be seen that in almost every case some improvements or developments have taken place since the first cars were introduced on the respective lines herein dealt with.

It may be taken that self-contained railway motor cars are essentially useful for the opening up of new traffic, and also for dealing with small traffic in sparsely populated districts.

They are also most useful for small and frequent services, between points of moderate distance apart, and for suburban traffic generally, where it is not too heavy.

The drawings and particulars attached to this report will enable all to appreciate the general design and construction of these self-contained cars.

It may be stated broadly that the majority of railway companies in Great Britain use small boilers of locomotive type for their steam motor cars, such as the London & North Western Railway, Lancashire & Yorkshire Railway, and a few others, whilst the Great Western Railway, and some other companies use vertical boilers with multiple tubes. The Taff Vale Railway use a special boiler with a locomotive fire-box in the middle, and two short barrel ends fitted with a number of small

*

tubes. This boiler in fact is after the style of the boiler used many years ago in Fairley's double ended locomotives.

It may also be stated that the Lancashire & Yorkshire Railway, and a few others use the Walschaerts Gear for the motion, while the remaining companies use the ordinary Stephenson or straight link motion.

The speeds attained with these motor cars range from 45 miles per hour on some lines down to 25 miles per hour on others, and these cars whenever needed can negotiate inclines as steep as one in 38.

So much for the initiatory stages of railway motor car service.

The next development to be referred to is where these small cars are made to take with them, when necessary, another, or trailing car, to meet the increase in passengers at certain periods of the day.

The third stage is where these self-contained motor cars have a carriage attached to them, generally speaking, in front of the engine, and so fitted, that the motor car engine which pushes it along, may be actuated and controlled from a compartment in the leading end of this carriage.

A still further development is that of an ordinary locomotive, of small type, specially fitted, and placed between two carriages — each of these carriages being equipped with a drivers compartment, at the end farthest from the engine so as to enable the engine to be actuated from either one of these compartments, whichever happens to be leading.

From this compartment the driver, who rides in it, has complete control of the train, the fireman, or assistant motorman remains on the footplate to attend to the engine, there being electrical communication between the motorman and his assistant.

The foregoing covers the various arrangements which are in existence for this particular class of traffic, and the particulars attached will in each case show the details of the several arrangements in use on the different lines reported upon.

To summarise. To enable the railway companies to meet the competition which had arisen in many suburban districts with electrical and other cars for street traffic, they were compelled to seek a method of providing a much more frequent service, and at the same time, one that could be worked at a much less cost per mile, than had been possible before with ordinary suburban trains. This object has been largely achieved by the adoption of these self-contained motor cars and motor trains, so far as, what may be termed " longer distance " traffic is concerned, and which otherwise might have been carried by street cars. It will of course be realised that railway companies cannot successfully compete with what we may call " door to door traffic ", but wherever passengers require to go a mile or two, the increased speed of the railway, makes their motor car service attractive to the public, as well as profitable to themselves, the cost per mile being about one third of what it is with an ordinary passenger train.

It seems to me that the drawings and particulars supplied herewith will make the

matter perfectly clear to those who desire information on the subject. I think perhaps it may be advisable for me to say, as one who has had a good deal of experience in the desiging and running of these motor cars, that any man who aims a designing motor cars will find it not nearly so simple a matter as designing an ordinary locomotive.

There are so many little and intricate circumstances and conditions, which bear upon and influence one another, that before anyone attempts to build a motor car, it is quite essential that every circumstance likely to arise in connection with such a vehicle, should be most carefully considered.

The following is a list of the railway companies who have replied to the questions :

Alexandra (Newport) Docks and Railway Company;
Furness Railway Company;
Great Central Railway Company;
Great Western Railway Company;
Lancashire & Yorkshire Railway Company;
London & North Western Railway Company;
London, Brighton & South Coast Railway Company;
Midland Railway Company;
North Staffordshire Railway Company;
North Eastern Railway Company;
Port Talbot Railway & Docks Company;
Rhymney Railway Company;
South Eastern & Chatham Railway Company;
Taff Vale Railway Company;
Dublin & South Eastern Railway Company (Ireland);
Great Northern Railway Company (Ireland);
Central South African Railway Company;
South Australian Government Railways;
Great Indian Peninsula Railway Company;
Madras & Southern Mahratta Railway Company;
North Western State Railway of India.

*

APPENDIX I.

Summary of replies to detailed list of questions relating to question XII.

QUESTION 1. — *Description of railway auto-motor cars. — a) What are the various types of automotor cars or motor luggage vans in use on the railway. — b) If driven by steam, oil gas or electricity.*

The following railways have automotor cars in use, driven by steam, except where otherwise stated. The principal type is with engine and car combined, capable of being driven from the car end as well as from the engine.

On some of the lines, as stated against them, they run an ordinary locomotive of small type either with one carriage attached, capable of being driven from the leading end of carriage as well as from the engine, or with the engine placed between two carriages, also capable of being driven from either end according to which carriage is leading.

These are referred to below (where in use) for the sake of brevity as "Short Motor Trains".

The various types of auto-car are shewn on the drawings supplied.

REPLIES OF RAILWAYS TO WHICH ABOVE REMARKS APPLY.

Alexandra (Newport) Docks & Railway Company. — Ordinary type. Combined engine and car.

Furness Railway. — Ordinary type. Combined engine and car.

Great Central Railway. — Ordinary type. Combined engine and car.

Great Western Railway. — Ordinary type. Combined engine and car; Also "short motor trains".

Lancashire & Yorkshire Railway. — Ordinary type. Combined engine and car.

London & North Western Railway. — Ordinary type. Combined engine and car.

London, Brighton & South Coast Railway. — Class 1 : Auto steam car. Combined engine and car. Class 2 : "Short motor train". Class 3 : Petrol engine coaches with motor of pleasure road car type. Class 4 : Petrol Electric Coaches. Petrol motor driving dynamo to charge accumulators which afterwards drive the car, the dynamo becoming the motor and the petrol engine assisting if necessary.

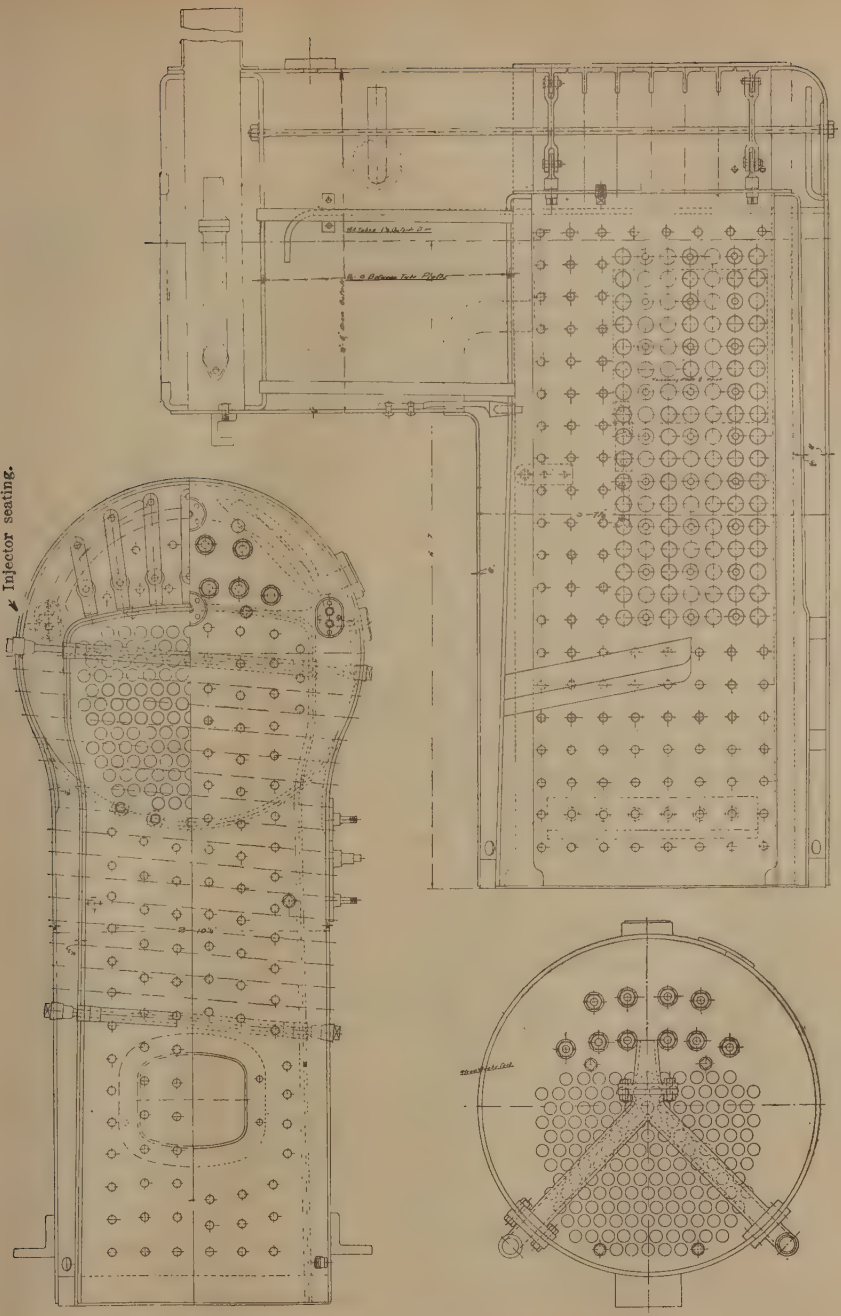

Fig. 1. — Alexandra (Newport) Docks & Railway. — Boiler No. 1 steam motor carriage.

Heating surface of smoke tubes	. . . . .	152	square feet.	
— — of water-tubes	. . . . .	119	—	—
— — of fire-box	. . . . .	76	—	—
Total.	. .	347	square feet.	

Fire-grate area : 7 square feet.

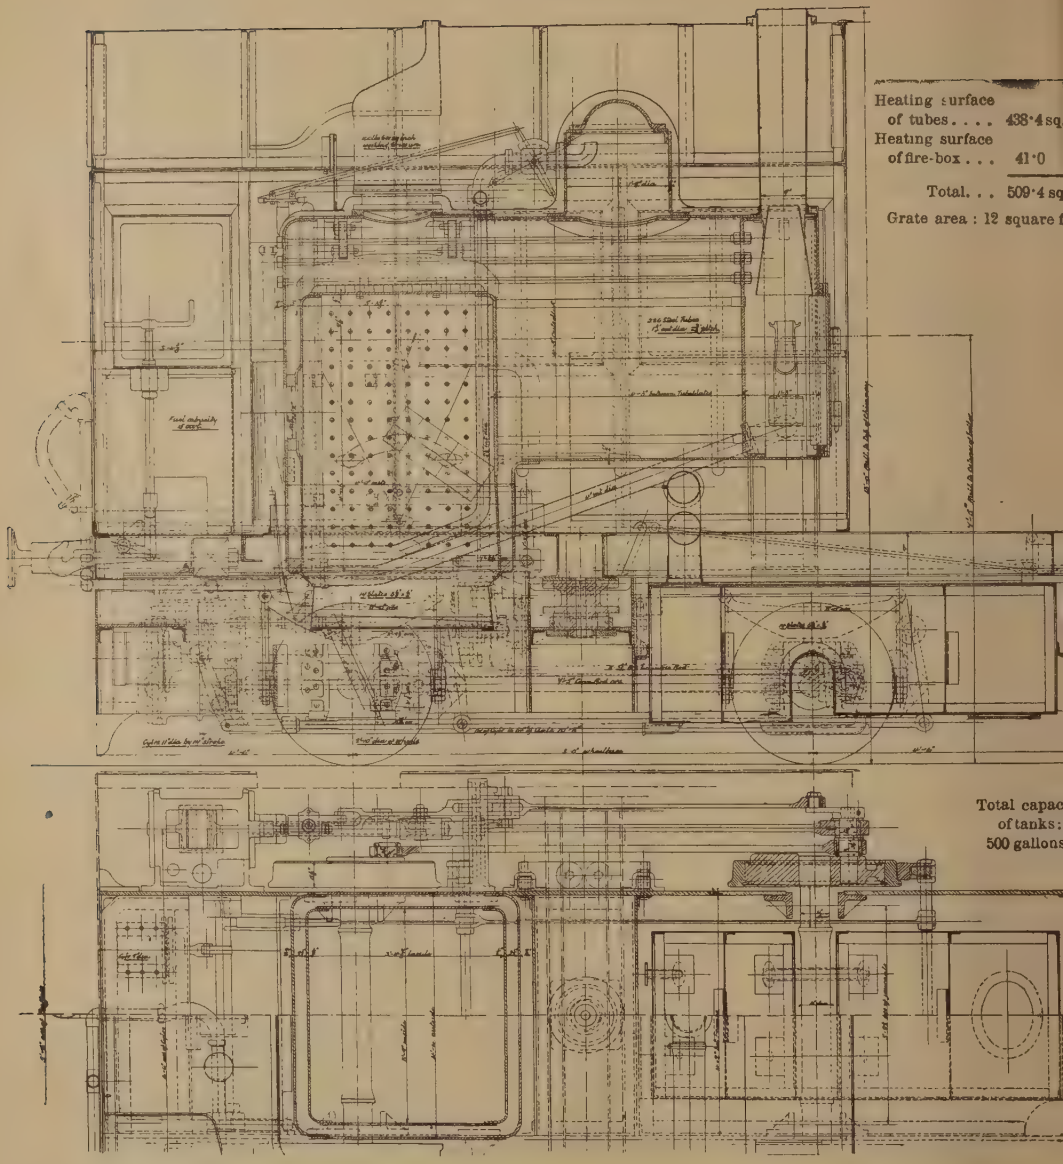

Fig. 2. — Furness Railway. — Steam motor engine.

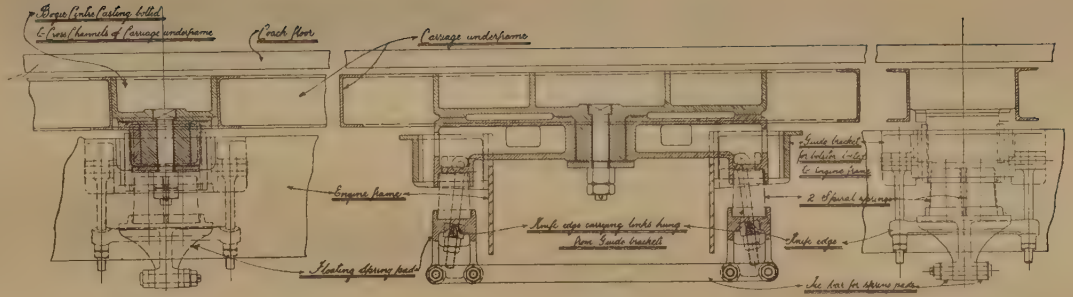

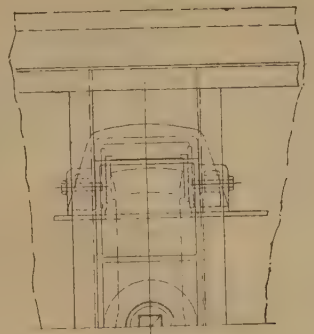

Half plan.

Fig. 3. — London & North Western Railway. – Steam rail motor carriage. — Sketch showing method of attaching engine to carriage.

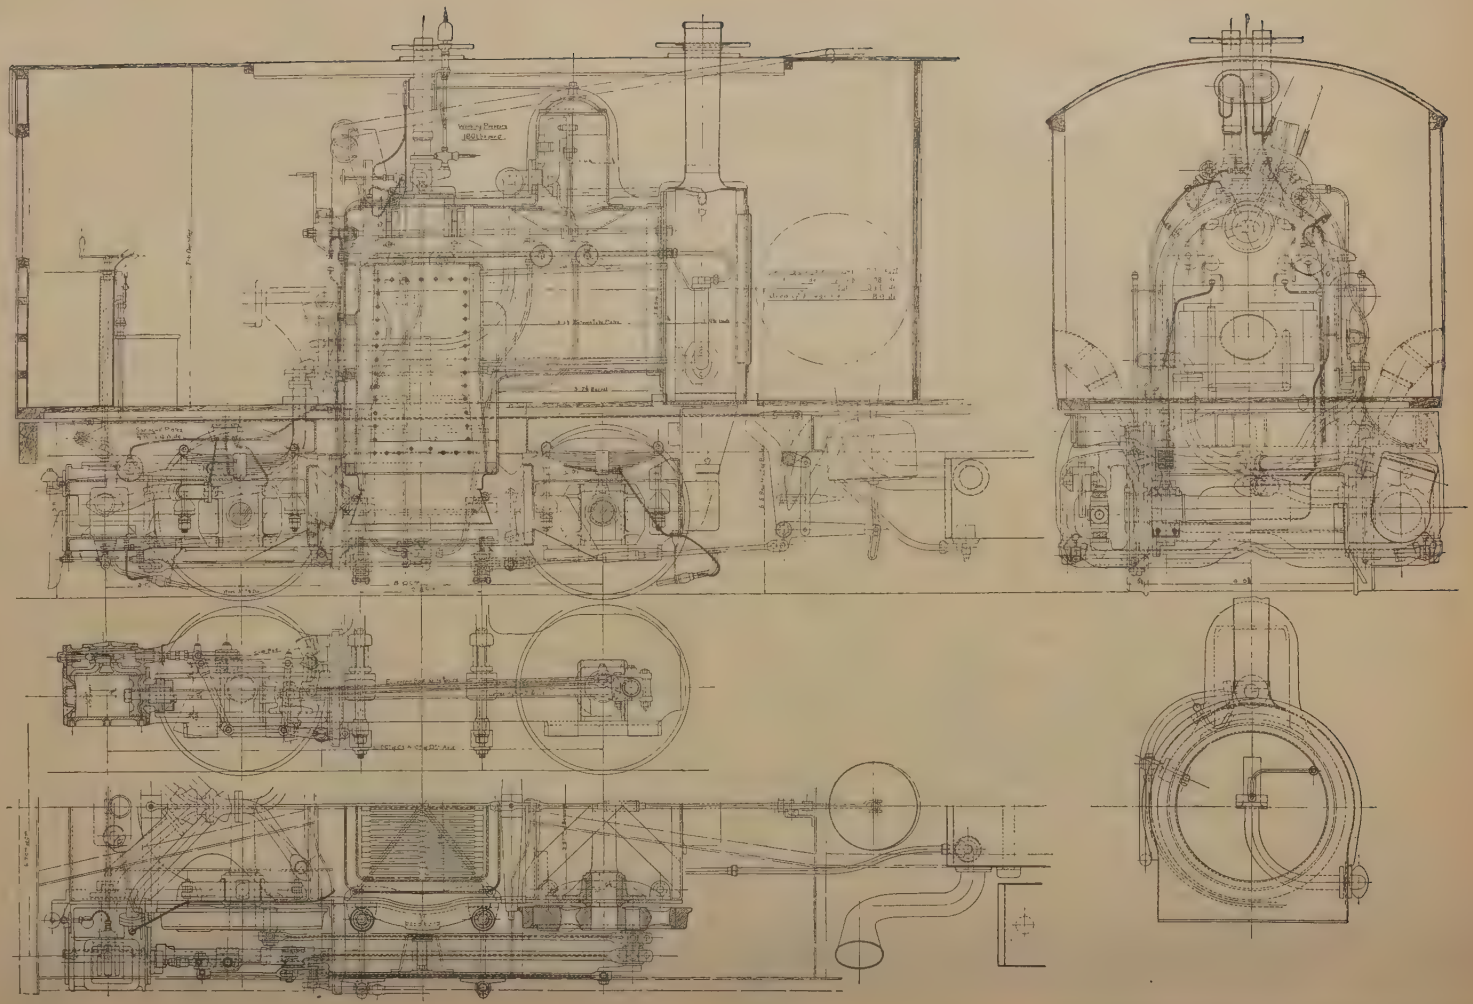

Fig. 4. — Midland Railway. — General arrangement of motor. — Steam motor carriage.

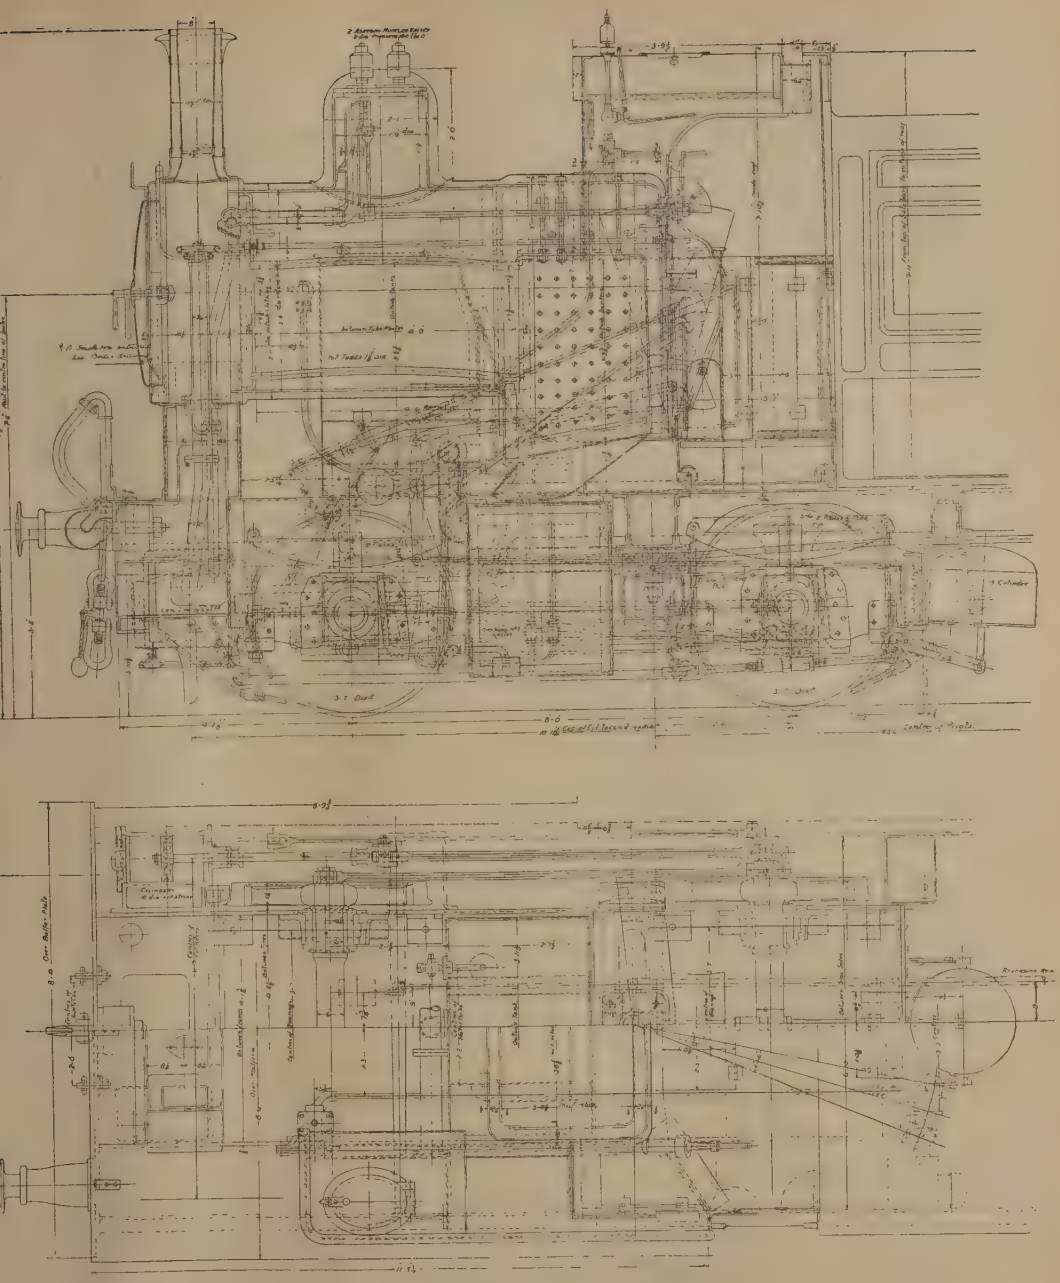

Fig. 5. — South Eastern & Chatham Railway.

Heating surface of tubes	337·0 square feet.	Grate area	8·8 square fee
— — of firebox	44·5 — —	Gauge of railway	4 ft. 8 1/2 in.
Total.	381·5 square feet.	Water	400 gallons.
		Coal	15 cw

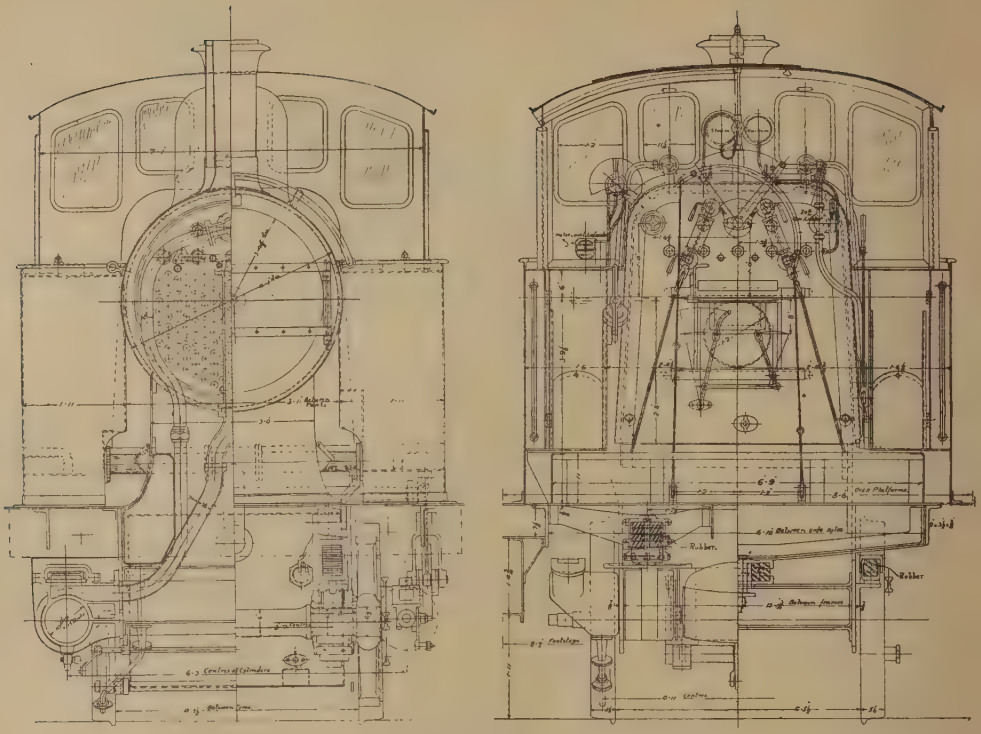

Fig. 6. — South Eastern & Chatham Railway. — Engine, steam motor coach.

Midland Railway. — Class 1 : Auto steam car. Combined engine and car. Class 2 : Pullman car with separate locomotive. Class 3 : " Short motor train ".

North Staffordshire Railway. — Ordinary type. Combined engine and car.

North Eastern Railway. — Petrol electric driven rail auto-cars. Petrol engine driving electric generator. " Short motor train ". (See appendix II.)

Port Talbot Railway. — Ordinary type. Combined engine and car.

Rhymney Railway. — Ordinary type. Combined engine and car.

South Eastern & Chatham Railway. — Ordinary type. Combined engine and car. Also " short motor trains ".

Taff Vale Railway. — Ordinary type. Combined engine and car. Also " short motor trains ".

Dublin & South Eastern Railway (Ireland). — " Short motor train " type only.

Great Northern Railway (Ireland). — " Short motor train " type only.

Central South African Railways. — Class 1 : Ordinary type. Combined engine and car. Class 2 : Small locomotive coupled by a " Gould " coupler to an ordinary coach.

South Australian Government Railways. — Ordinary type. Combined engine and car.

Great Indian Peninsula Railway. — Ordinary type. Combined engine and car.

Madras & Southern Mahratta Railway. — Ordinary type. Combined engine and car.

North Western State Railway of India. — Ordinary type. Combined engine and car.

QUESTION 2. — *Design of the automotor-car (elevation and plan), preferably to the scale of 3/4 inch to one foot.*

Please also show on plan : Driving axles ; coupled axles ; gauge of track ; section of rail ; distances from centre to centre of the axles and of bogies ; diameters of wheels respectively ; length over buffers ; length over body ; width over body ; width and the inner height of compartments ; maximum height from rail.

QUESTION 3. — *General design, with sections, of the motor, of the boiler (if any), and accessories, preferably to the scale of 3/4 inch to one foot.*

It would be advisable to have, apart from above, the most characteristic details of construction.

For automotors consisting of an independent engine, or else of an almost independent motor-truck, and of a car fastened to said engine, or else carried on one end by the underframe and on the other end by an axle or an ordinary bogie, please show how the car is joined to the engine.

RAILWAYS.	Question 7. — *Brake-gear*		Question 8. — *Heating and Lighting*	
	Description.	How acts.	Heating.	Lighting.
Alexandra (Newport) Docks & Railway Company	Steam and Screw.	Steam acts on 4 wheels at boiler end. Screw acts on all wheels.	Live steam.	Acetylene gas and electricity Outside lamps oil.
Furness Railway	Automatic Vacuum.	On all wheels.	Ditto.	Electric; outside lamps oil.
Great Central Railway	Automatic Vacuum and Screw.	On all wheels except leading wheels of independent engine.	« Gould's » steam.	Stones electric.
Great Western Railway	Ditto.	On all wheels.	Steam.	Incandescent oil gas. Petroleum, front and end lamps.
Lancashire & Yorkshire Railway	Ditto.	On all wheels. Separate screw brakes for engine and coach bogies to act as a stand by.	Gould's heaters.	Incandescent gas Footplate, front and tail lamps-oil
London & North Western Railway	Automatic Vacuum and hand.	On all wheels.	Steam.	Electric.: Front und tail lamps oil.
London, Brighton & South Coast Railway.	Westinghouse and hand	Ditto.	Nil.	Stones' electric.
Midland Railway	Class 1 : Vacuum.	Ditto.	Footwarmers.	Gas.
	Class 2 : Vacuum and steam.	Steam brake on engine. All wheels braked except engine bogie. All wheels on Pullman car-vacuum brake.	Ditto.	Gas. Drivers cab and outside lamps oil.
	Class 3 : Ditto.	Steam brake on engine. Vacuum brake on coaches.	Steam.	Gas.
North Staffordshire Railway	Automatic Vacuum.	Acts on all wheels.	Steam (Laycocks).	Electricity. Petroleum outside lamps.
North Eastern Railway.	Hand brake and Electro-Magnetic Track Brake.	Hand brake on one bogie only. Magnetic brake on both bogie wheels.	By radiator pipes of petrol engine.	Electricity.
Port Talbot Railway	Hand, Steam and Vacuum.	Hand brake at either end. Steam brake on engine wheels only. Vacuum on all wheels.	Gould's system.	Ditto.
Rhymney Railway.	Westinghouse and hand.	Westinghouse on all wheels excepting engine trailer wheels. Hand on engine leading and driving wheels and car bogie wheels.	Footwarmers.	Stones electric. Leading end of engine oil lamps.
South Eastern & Chatham Railway	Automatic Vacuum and Screw.	On all wheels.	Footwarmers.	Stones' Electric. Front and tail lamps oil.
Taff Vale Railway	Automatic Vacuum Steam and hand brake.	Ditto.	Steam. G. D. Peeters system.	Incandescent oil gas. Oil lamp for drivers cab und outside lamps.
Dublin & South Easter Railway	Automatic Vacuum.	Ditto.	Steam.	Incandescent gas. Head tail and side lamps oil.
Great Northern Railway Ireland)	Automatic Vacuum and hand brake.	Ditto.	Steam. Gould's system.	Stone's electric.
Central South African Railways.	Automatic Vacuum and hand brake.	On drinving pair of wheels only of locomotive and all wheels of coach bogies.	Steam. Laycocks system.	Ditto.
South Australian Railways	Westinghouse and hand.	All wheels.	Nil.	Stone's electric for car. Head and tail lamps oil.
Great Indian Peninsula Railway	Automatic and hand.	Dito.	Nil.	Electric.
Madras & Southern Mahratta Railway	Vacuum and hand.	Ditto.	Nil.	Gas inside car and outside car lamps. Outside lamps on engine oil.
North Western State Railway of India.	Vacuum Screw and Steam.	Vacuum on trailing end only. Screw on both bogies. Steam-engine end only.	Nil.	Gas and oil lamps.

QUESTION 9. — *Buffing Gear.*

Alexandra (Newport) Docks & Railway Company. — Normal type.

Furness Railway. — Normal type.

Great Central Railway. — Ordinary buffers of standard type.

Great Western Railway. — Standard buffing gear on ordinary cars. Central buffers when trailer is permanently attached.

Lancashire & Yorkshire Railway. — Normal type both ends.

London & North Western Railway. — Normal type with springs.

London Brighton & South Coast Railway. — Normal type.

Midland Railway. — Class 1 : Ordinary buffing gear. — Class 2 : Ordinary gear on car and front of engine. Solid beam at rear of engine. — Class 3 : Ordinary buffing gear.

North Staffordshire Railway. — Normal type.

North Eastern Railway. — Normal type.

Port Talbot Railway. — Normal type.

Rhymney Railway. — Normal type self contained.

South Eastern & Chatham Railway. — Buffing gear ordinary socket buffers on engine and car.

Taff Vale Railway. — Ordinary type.

Dublin & South Eastern Railway (Ireland). — Ordinary type.

Great Northern Railway (Ireland). — Ordinary type.

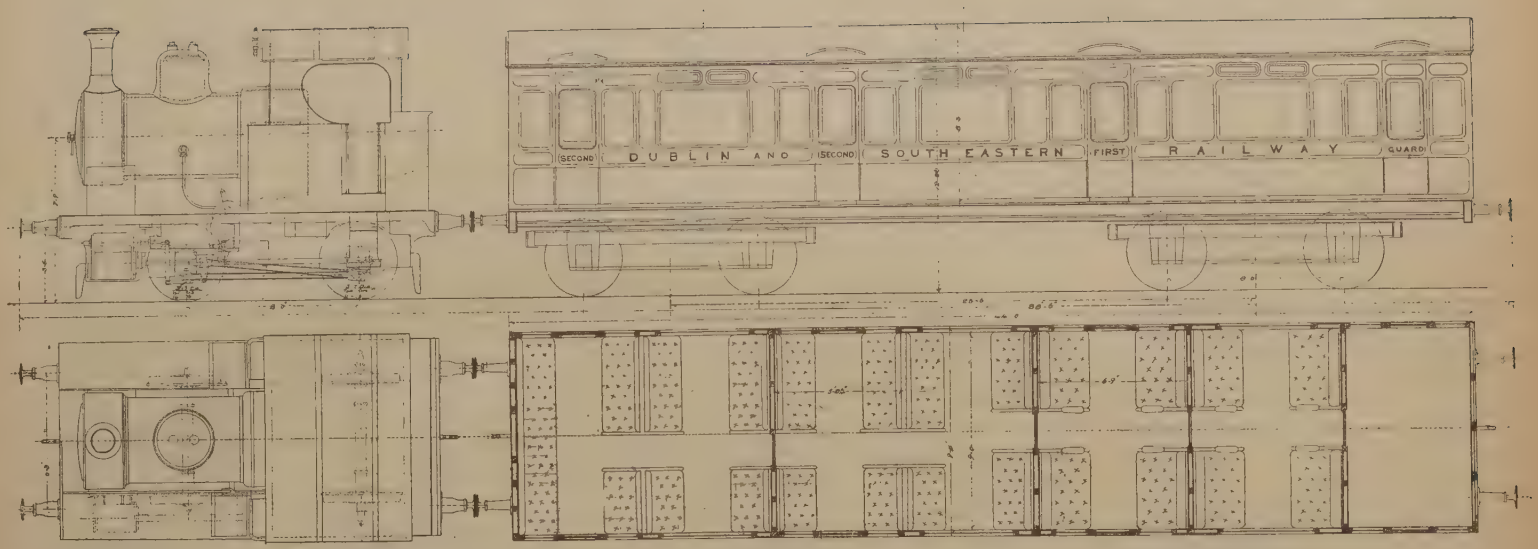
Central South African Railways. — Class 1 : Gould coupler between engine and coach Standard pattern for new coaching stock. — Class 2 : Central buffers (Cape pattern) being standard for all wagon stock.

South Australian Government Railways. — Normal type.

Great Indian Peninsula Railway. — Normal type of compensating buffer gear.

Madras & Southern Mahratta Railway. — Normal type.

North Western State Railway of India. — Standard gear.



Cylinders	12 × 16 inches.
Gauge of railway	5 ft. 3 in.
Water	540 gallons.
Coal	1 1/4 tons.

Boiler pressure	175 lb. per square inch.
Heating surface in fire-box	45 square feet.
— — in tubes	441 — —
Total	486 square feet.
Grate area	9·5 square feet.

QUESTION **11**. — *Relating to explosion automotor cars.*

London, Brighton & South Coast Railway. — Class 3 : Two 4-cylinder motors, cylinder 124 millimetre (4 $^{7}/_{8}$ inches) diameter by 150 millimetres (5 $^{15}/_{16}$ inches) stroke. Ignition by accumulator dryving one axle by friction clutch and spur gearing. — Class 4 : One 4-cylinder motor. Cylinders 180 millimetres (7 $^{1}/_{16}$ inches) diameter by 150 millimetres (5 $^{15}/_{16}$ inches) stroke. Drives dynamo through magnetic clutch which is automatically released at a certain voltage. The dynamo charges accumulators and when the potential is reached, the dynamo becomes motor and drives one axle through spur gearing.

North Eastern Railway. — See separate description appended (appendix II).

None of the other railways dealt with have these cars running.

QUESTION **12**. — *Relating to cab arrangements for driving from either end, according to whether the engine or car end is leading.*

Alexandra (Newport) Docks & Railway Company. — Cab at each end for driver. The auxiliary cab is fitted with an arrangement for reversing and is also connected to the regulator valve by means of levers and rods which can be opened and closed. Intercommunication with the cab of the engine by means of electric ringing.

Furness Railway. — Two similar cabs with outfits at each end. Electric ringing used for intercommunication. Whistle and regulator coupled by means of wire rope. Guard controls valve for use of brake.

Great Central Railway. — Electric bell and speaking tube communication. Steam whistle operated by wire cord. Regulator operated by rod and universal joints for both closing and opening. Screw brake on all wheels of coach only, vacuum brake on all wheels including engine. Reversing gear of engine. Sand gear on wheels of coach.

Great Western Railway. — Engine cab at one end and vestibule with regulator handle, hand brake lever, vacuum brake cock. Electric communication and whistle connection at other end.

Lancashire & Yorkshire Railway. — In addition to the cab on the engine, there is a driver's compartment at the rear end fitted with the following appliances — regulator handle which can open or shut off steam to the engine ; this handle has a spigot and socket connection, and it is so arranged that the driver must carry it with him when he goes to drive at the opposite end of the coach. Vacuum brake application valve which will operate the brakes on both the engine and coach bogie wheels. Screw gear to operate the coach bogie wheels only. Lever and cord arrangement for blowing the whistle on engine. Electric bell and switch for signalling purposes between engine cab and driver's compartment. Vacuum application valve for operating the steps. A vacuum gauge.

London & North Western Railway. — There is the compartment proper at the engine end and an auxiliary compartment at the opposite end of the car, from either of which the car can be driven in either direction. When driving from the auxiliary compartment, the driver has full control of the engine regulator, the automatic vacuum brake and the hand brake. In addition

he can communicate with the fireman in the engine cab by means of a code of electrical signals given on a gong.

London Brighton & South Coast Railway. — Class 1 : Ordinary tank engine covered cab compartment for driver at end of coach when running coach first. Compartment contains regulator handle, electric bell and push. Compressed air whistle lever, wire pull to engine whistle, drivers B. V. for Westinghouse brake and screw hand brake operating all wheels of trailer coach. Regulator works open and shut by universal coupling between engine and coach. — Class 2 : Cab covering all except smokebox and chimney. Compartment at end of coach for driver when running coach first. Compartment contains regulator handle electric bell and push. Compressed air whistle lever, wire pull to engine whistle, driver's B. V. for Westinghouse and screw hand brake operating all wheels of trailer coach. Regulator works open and shut by universal coupling between engine and coach.

Midland Railway. — Class 1 : Engine and cab at one end and cab at other end. — Class 2 : Cab at end of coach remote from engine. Both classes car travel backward at will.

System of operation. — Vacuum brake and whistle can be operated from both ends of train. The main steam regulator can be operated by wire ropes from cab for a supplementary regulator placed between ordinary regulator and cylinders. There is an electric signalling apparatus between driver and fireman for notching up and reversing purposes. — Class 3 : Cabs at ends of coaches remote from engine. Can travel backward at will. System of operation. Vacuum brake and whistle can be operated from both ends of train. There is a vacuum controlling gear.

North Staffordshire Railway. — One cab at engine end but when car is running backwards the fireman (who is a passed driver) stands in the vestibule at other end of car and there he is able to close the regulator, etc. In the vestibule at end of car used in running backwards as an auxiliary cab, levers are arranged for closing the regulator (not opening) and opening the steam whistle ; also there is a valve for applying the brakes and an electric bell for signals to the driver in engine cab.

North Eastern Railway. — Driver's cab at each end. Each cab provided with levers, brakes and controller for complete operation of the car. Engine under control of driver from either end. Whistle blown by compressed air, supplied from electrically driven air compressor.

Port Talbot Railway. — Fitted with sand boxes on the vestibule end. A complete engine at one end with an auxiliary cab at the other end occupied by driver when travelling backwards. The outfit of the auxiliary cab comprises regulator lever, vacuum ejector, hand brake, lever controlling sand gear whistles and electric bell. Signalling between driver and fireman is done by means of an electric bell.

Rhymney Railway. — Driver's cab on engine when travelling backwards the driver is in the car end. Intercommunication with the trailing end of car and engine, by means of electric bell ringing. The regulator can be worked from the rear end of car, also the continuous brake, hand brake (car only) and steam whistles.

South Eastern & Chatham Railway. — One cab on engine only. A luggage and driver's compartment at one end of car. The driver's compartment at one end of car is fitted with steam regulator closed and open, reversing gear, automatic vacuum brake application only. Screw brake on car bogie only. Steam whistle gear. The means of intercommunication with engine cab — a system of electric bell ringing is employed.

Taff Vale Railway. — The motor driver travels on foot-plate of engine together with the assistant motorman when running forward. For backward running driver stands in special compartment at end of coach and communicates with the assistant motorman by means of electric bells. The motor driver, when standing in this compartment has direct communication to the steam whistle on engine and also has control of a hand screw brake fitted therein. The regulator is opened and closed by the assistant motorman standing on the footplate of engine on receiving the signal from the motor driver.

Great Northern Railway (Ireland). — Electric bell communication Phaburn's mechanical telegraph for reversing twine cord for steam whistle. Regulator may be opened or closed and brake applied.

Central South African Railways. — The driver's compartment or auxiliary cab of these cars is fitted with gear for controlling the regulator, valve gear, brake, and apparatus for operating the engine steam whistle. Communication between the driver and conductor is provided for by a system of bell signals.

South Australian Government Railways. — No. 1 car has only one cab, No. 2 being fitted, with two. The auxiliary cab of No. 2 car is fitted with reversing gear and regulator handle. Communication is established by means of an electric bell. The driver also has control of the steam whistle. Air brake can be applied only.

Great Indian Peninsula Railway. — Cab on engine end, regulator handle, whistle handle and brake valve at end of car and on the engine. Electric bell code signals between driver and guard. In cases of emergency guard can close regulator and apply brakes.

Madras & Southern Mahratta Railway. — 1 cab engine and guard's compartment used by driver when running backwards regulator lever attached to regulator in guards oompartment by wire. See ferrotype No. 7660. Regulator handle, whistle cock, vacuum brake lever, vacuum gauge, hand brake and reversing gear. Intercommunication cord with whistle gear.

North Western State Railway of India. — Cab at engine end and cab at carriage end to enable car to be worked from either end. Complete controlling gear and speaking tubes.

QUESTIONS **13** AND **14**. — *a) Whether it is intended to adopt for local or light trains, specially designed small locomotives instead of automotor cars, with a view to attaining an economical service. If so please furnish particulars. — b) If not possessing specially designed small locomotives for such a service, please give particulars of locomotive of lightest type now in service.*

Alexandra (Newport) Docks & Railway. — *a)* Yes but have no designs.

Furness Railway. — *a)* No.

Great Central Railway. — *a)* No.

Great Western Railway. — *a)* We use small locomotives specially fitted with gear for driving from trailer cars attached at either or both ends of locomotive.

Lancashire & Yorkshire Railway. — *a*) No. — *b*) Particulars of the lightest type of passenger engine we have in service. Type 4-4-0 class. Cylinders 17 $^1/_2$ × 26 inches stroke. Steam ports 15 × 1 $^1/_4$ inches. Exhaust 15 × 2 $^3/_4$ inches. Boiler 10 ft. 3 in. long × 4 ft. 2 in. inside diameter. Fire-box shell (round top) 5 ft. 2 $^5/_8$ in. × 3 ft. 9 in. Inside copper fire-box 5 ft. 2 $^3/_8$ in. long by 3 ft. 9 in. wide × 5 ft. 4 $^3/_4$ in. deep at front end × 4 ft. 2 $^3/_4$ in. deep at back end. Heating surface of fire-box, 90·5 square feet; heating surface of tubes, 943·5 square feet; total, 1,034·0 square feet. Number of tubes 194 × 1 $^3/_4$ inches outside diameter. Grate area 19·25 square feet. Diameter of bogie wheels 3 ft. 7 $^3/_4$ in. Diameter of coupled wheels 6 feet. Diameter of tender wheels 3 ft. 7 $^3/_4$ in. Water capacity of tenders 2,000 gallons. Coal capacity of tender 4 tons.

	Empty.	Working order.
Total weight on bogie.	12 t. 0 c. 2 q.	12 t. 12 c. 2 q.
Pair driving wheels.	13 t. 19 c. 0 q.	15 t. 11 c. 0 q.
— trailing wheels.	12 t. 11 c. 3 q.	14 t. 1 c. 0 q.
— leading tender wheels	6 t. 1 c. 0 q.	9 t. 10 c. 0 q.
— intermediate tender wheels. . .	5 t. 13 c. 0 q.	8 t. 16 c. 0 q.
— trailing tender wheels.	5 t. 0 c. 0 q.	9 t. 3 c. 0 q.
	55 t. 5 c. 1 q.	69 t. 13 c. 2 q.

London & North Western Railway. — *a*) No. — *b*) We work our light passenger trains with tank locomotives.

London Brighton & South Coast Railway. — *a*) Class 1 : No the small locomotives adopted to haul and push trailer cars are found to meet all requirements.

Midland Railway. — *a*) A small type of existing engine has been adopted to suit requirements.

North Staffordshire Railway. — *a*) No.

North Eastern Railway. — *a*) We have made a combination of engine and carriage by utilising some of our lighter engines and attaching to them a carriage with an arrangement for driving the engine from the other end of the carriage. See appendix II. They are not however strictly speaking, automotor cars.

Port Talbot Railway. — No.

Rhymney Railway. — No.

South Eastern & Chatham Railway. — *a*) We are building two small locomotives for working light trains instead of automotor cars. These small engines have inside cylinders 12 inches diameter × 18 inches stroke 6-coupled wheels 3 ft. 9 in. diameter side tanks with coal bunkers at back end. Ordinary locomotive type of boiler 440 square feet heating surface; 9 square feet grate. Working pressure 180 lb. per square inch. Weight empty about 19 tons. Full weight at work about 24 tons. Load per pair of wheels about 8 tons.

Taff Vale Railway. — *a*) We have fitted up a small locomotive to run between two coaches forming a "motor train" capable of being driven from either end, from a specially equipped compartment, in which the motorman rides, and whence he has complete control of the train. The assistant motorman remains on the foot plate to attend to the engine there being electrical communication between the motorman and his assistant. We have two of these motor trains on service. One coach has seating accommodation for 86 passengers (16 first, 42 non-smoking

3rd and 28 3rd smoking class) and the other 80 passengers (56 non-smoking and 24 smoking all 3rds). Total per train 166 passengers. The trains are lighted by incandescent gas and heated by steam, G.-D. Peters' system.

Weight of engine in working order :

Bogie.	14 t. 4 c.
Driving wheels	15 t. 10 c.
Trailing wheels.	15 t. 14 c.
Total.	45 t. 8 c.

Dublin & South Eastern Railway. — *a*) Yes-have adopted light locomotives. See figs. 17 & 18.

Great Northern Railay (Ireland). — *a*) No. Special engines have been designed for this service but small bogie tank engines are used.

Central South African Railways.— It is not contemplated to specially design small locomotives for light trains. Should our present motor car service require extension, we have several such locomotives too light for other work, at present lying idle. A suitable coach would be designed for attachment to these engines.

South Australian Government Railways. — No.

Great Indian Peninsula Railway. — We have considered the adaptibility of small tank engines which have seen many years service and are now obsolete. One has been fitted up and is now in service.

Madras & Southern Mahratta Railway. — Yes. — It is contemplated to use some small tank locomotives.

II. — Organization of the service and modus of working.

QUESTION 1. — *a*) *Whether motor cars are worked alone or with trailers.* — *b*) *If trailers used, is there intercommunication between motor cars and trailer.* — *c*) *If continuous brakes used exclusively.*

Alexandra (Newport) Docks and Railway. — *a*) We used them with trailing cars. — *b*) No. — *c*) Continuous brakes not used.

Furness Railway. — *a*) Trailing cars. — *b*) Yes. — *c*) Yes.

Great Central Railway. — *a*) Trailing cars. — *b*) No. — *c*) Yes.

Great Western Railway. — *a*) They work alone or with trailers attached as required. — *b*) In cases where a small locomotive is employed with two trailer cars attached at each end, intercommunication is provided between the trailers.

Lancashire & Yorkshire Railway. — *a*) Eight cars are designed to work exclusively isolated, but six of these haul an extra-ordinary coach during heavy traffic. Seven other cars have been designed to work exclusively or to haul a specially designed trailer car. — *b*) Yes. — *c*) The automatic vacuum brake is continuous — the brake valves operate both cars.

London & North Western Railway. — *a*) Isolated — no trailing cars allowed. — *c*) Yes when running; a hand brake is provided for occasional use if required.

London Brighton & South Coast Railway. — *a*) Are used with standard coaches attached on special occasions. — *b*) No. — *c*) Class 1 : Yes. Class 2 : The brake being the automatic vacuum precludes this unless extra coach happens to be dual fitted.

Midland Railway. — *a*) Class 1 : One trailer is allowed. Classes 2 and 3 : Equal to two extra vehicles fully fitted may be conveyed in the rear of any of these trains when necessary. — *b*) In each class, the control is limited to that of part the arrangement distinct from the trailers, except so far as braking is concerned over which the guard has control, and his position is in the rear of the train. — *c*) See question 1-B 7 for braking. All vehicles used are vacuum fitted.

North Staffordshire Railway. — *a*) Not exclusively isolated always. Sometimes use one or more trailer cars but motor cars were only designed to haul one trailer car. — *b*) No. — *c*) Yes.

North Eastern Railway. — *a*) Isolated. — *c*) No.

Port Talbot Railway. — *a*) Trailer used when required. — *b*) No. — *c*) Yes.

Rhymney Railway. — *a*) With trailing cars. — *b*) No. — *c*) Yes except that one vehicle without continuous brake may be taken in rear.

South Eastern & Chatham Railway. — *a*) We employ cars isolated and with trailing cars. — *b*) There is no intercommunication between the automotor car and the trailing car. — *c*) Plant with continuous brakes used exclusively.

Taff Vale Railway. — *a*) Principally with trailing coaches. — *b*) Yes. — *c*) Yes.

Dublin & South Eastern Railway (Ireland). — *a*) Usually with trailers. — *b*) No. — *c*) Yes.

Great Northern Railway (Ireland). — *a*) With trailing cars. — *b*) No. — *c*) Yes.

Central South African Railways. — *a*) Both types of our cars are used isolated. No trailers are attached.

South Australian Government Railways. — *a*) The only trailing vehicle used with these cars is a small covered goods van weighing 3 tons 11 cwts, limited to a load of 6 tons. There is no means of communication between the van and car.

Great Indian Peninsula Railway. — *a*) Employed exclusively isolated. — *c*) Yes.

Madras & Southern Mahratta. — *a*) Both. — *b*) No. — *c*) Yes.

QUESTION 2. — *a*) *Number of "Traction Agents" employed.* — *b*) *Number of "Working Agents" employed.* — *c*) *Whether the number of men is the same when taking a trailer as when running alone.*

Alexandra (Newport) Docks and Railway. — *a*) The mechanical working of the car is in charge of a driver assisted by a fireman. — *b*) A conductor.

Furness Railway. — *a*) Two. — *b*) Two. — *c*) Yes.

Great Central Railway. — *b*) Two men employed on all cars and no more.

Great Western Railway. — *a*) Two (engineman and fireman). — *b*) One (conductor). — *c*) On branch and main line long distance services, one conductor as guard. On suburban services one conductor to each car owing to passage not being provided between the cars.

Lancashire & Yorkshire Railway. — *a*) The handling of each car is entrusted to three men, driver, fireman and conductor.

London & North Western Railway. — *a*) Two. — Driver and stoker. — *b*) One attendant is attached to each car.

London Brighton & South Coast Railway. — *a*) Classes 1 and 2 : Two. — Classes 3 and 4 : One. *b*) One. All classes. — *c*) Staff remains the same. All classes.

Midland Railway. — *a*) Driver and fireman. — *b*) Guard. — *c*) Same staff under all conditions.

North Staffordshire Railway. — *a*) Two motormen are always employed, one being an established locomotive driver and the other a "passed" driver, as he is practically in charge of the car when running backwards. — *b*) Guard.

North Eastern Railway. — *a*) One driver only. — *b*) One guard.

Port Talbot Railway. — *a*) One. — *b*) Nil.

Rhymney Railway. — *a*) Driver and stoker. — *b*) One conductor.

South Eastern & Chatham Railway. — *a*) Driver and stoker. — *b*) One guard. — *c*) Same staff in all cases.

Taff Vale Railway. — *a*) One motorman and assistant. — *b*) One conductor. — *c*) The number of conductors depend on the number of trailer cars.

Dublin & South Eastern Railway. — *a*) See question 5. — *b*) One. — *c*) Same staff.

Great Northern Railway (Ireland). — *a*) One only. Fireman remains at boiler.

Central South African Railways. — *a*) Driver and fireman. — *b*) Conductor-examiner.

South Australian Government Railways. — *a*) No. 1 car : Driver. — *b*) No. 1 car : Guard. *a*) No. 2 car : Driver and fireman. — *b*) No. 2 car : Guard.

Great Indian Peninsula Railway. — *a*) Driver and fireman. — *b*) Guard.

Madras & Southern Mahratta Railway. — *a*) Two. — *b*) Guard and fireman.

Question 5. — *a*) *If necessary to turn the motor car on a turntable at end of journey.* — *b*) *Whether any difference is made in speed when running "engine" end first or car end first.* — *c*) *If more than one car is attached, is it put on in front or behind.*

Alexandra (Newport) Docks and Railway. — *a*) No. — *b*) No. — *c*) We always attach the additional cars on behind.

Furness Railway. — *a*) No. — *b*) No. — *c*) No.

Great Central Railway. — *a*) Cars are drawn from either end.

Great Western Railway. — *a*) No. Driver always at leading end. — *b*) No difference in speed whichever way cars run. — *c*) Cars allowed to push one vehicle specially fitted with controlled gear at the outer end similar to that provided in driver's vestibule of motor car. No difference in speed.

Lancashire & Yorkshire Railway. — *a*) No. — *b*) No. The cars travel at 40 miles per hour in either direction. — *c*) Only one car is allowed to be attached. The specially constructed trailer car fitted with driving appliances is propelled, but the ordinary car is always drawn.

London & North Western Railway. — *a*), *b*) and *c*) No.

London Brighton & South Coast Railway. — *b*) No restrictions except by booked times, which allow of an average speed, deducting stops, of about 30 miles per hour in either direction. — *c*) The regular attached coach only is allowed to be pushed. The extra coach is attached to end of trailing coach or leading end of engine according to direction run.

Midland Railway. — *a*) and *b*) We have no cars with single cab and no turn-table is necessary as in each case the cars can be and actually are run in either direction as required. The maximum speed is 35 miles per hour. — *c*) Extra vehicles are always taken in the rear of the train.

North Staffordshire Railway. — *b*) No difference in speed when running in either direction. — *c*) No. Any cars attached to motor cars are always hauled, not pushed.

North Eastern Railway. — *b*) Full speed — no matter which end running in front. — *c*) No; single auto. only.

Port Talbot Railway. — *b*) 30 miles per hour either way.

Rhymney Railway. — *a*) Cars not turned as engine can be worked from either end of car. — *b*) 40 miles per hour. — *c*) No. Additional cars are always attached in the rear.

South Eastern & Chatham Railway. — *b*) 40 miles per hour from either end. — *c*) Cars are not pushed. The automotor shunts at end of journey. Additional cars always attached behind and drawn.

Taff Vale Railway. — *a*) No. The motorman travels on the engine in one direction and in a compartment of a carriage in the opposite direction and indicates to the Assistant by a code of signals the proper time to start and stop. — *b*) There is no limit to the speed in any direction under the maximum limit for both directions. — *c*) We do not practise this mode of working.

Dublin & South Eastern Railway (Ireland). — *a*) Engine is shunted around train. — *b*) and *c*) No.

Great Northern Railway (Ireland). — *a*) No cars like this. — *b*) Speed same in each direction. — *c*) Only one car attached to motor car and it is drawn on one journey and pushed on return journey.

Central South African Railways. — *b*) Maximum speed 40 miles per hour (Class 1). — Maximum speed 30 miles per hour (Class 2).

South Australian Government Railways. — *a*) Yes. — *b*) 26·3 miles average speed both ways.

Great Indian Peninsula Railway. — *a*) No. — *b*) Same speed as when running engine leading. — *c*) A second car could be worked if desired, attached behind.

Madras & Southern Mahratta Railway. — *b*) Maximum speed same in both cases. — *c*) No.

*

North Western State Railway of India. — *b*) 26 miles per hour booked speed irrespective of which end is leading. — *c*) No pushing allowed. Attached cars trailing.

QUESTION 4. — *Does the driver when travelling car end first, ride in the auxiliary cab and the stoker remain in the engine cab or vice-versa ?*

Alexandra Newport Docks & Railway. — The driver takes his post in the auxiliary cab when the car travels backwards, and the stoker remains in the engine cab.

Furness Railway. — Stoker always remains in engine cab.

Great Central Railway. — Driver in front. Fireman always on engine.

Great Western Railway. — Yes. Driver always at leading end and fireman always in engine cab. (Driver and fireman together when travelling in one direction and separated when travelling in the other.)

Lancashire & Yorkshire Railway. — Yes. The driver goes to the auxiliary cab. Stoker remains on engine.

London & North Western Railway. — The driver, when the car is travelling backward, takes his place in the auxiliary compartment, and the fireman or stoker remains in the engine compartment.

London, Brighton & South Coast Railway. — Driver and stoker on engine when pulling. Driver in car cab compartment and stoker on engine when pushing.

Midland Railway. — The driver is in all cases at the front of the car, that is, in the auxiliary cab when this is in front, and then the stoker is not with the driver.

North Staffordshire Railway. — Driver always remains in engine cab, and assistant driver goes to auxiliary cab when running backwards.

North Eastern Railway. — Only one motorman employed and he always in the leading cab. Driver always in the leading cab. Guard in the rear cab.

Port Talbot Railway. — Yes.

Rhymney Railway. — The driver works in the auxiliary cab and the stoker in the engine cab.

South Eastern & Chatham Railway. — The driver in the case of travelling backwards takes his post at the drivers compartment at the end of car. Stoker remains on engine.

Taff Vale Railway. — Yes.

Great Northern Railway (Ireland). — Driver is always in front cab.

Central South African Railways. — When travelling backwards in both cars, the driver operates the car from the drivers compartment or auxiliary cab at end of coach, the fireman remains on the locomotive footplate.

South Australian Government Railways. — The driver takes his place in the auxiliary cab and the fireman on the engine.

Great Indian Peninsula Railway. — Yes.

Madras & Southern Mahratta Railway. — Yes.

North Western State Railway of India. — Driver always in leading end.

QUESTION 3. — *a) In the case of small locomotives (questions 1 to 13) is the handling entrusted to one man only. — b) Are the motor cars and their trailers fitted with continuous brakes. — c) Is there intercommunication with the car and trailer. — d) If any arrangement adopted for continuous automatic feeding of fire-box.*

Alexandra (Newport) Docks and Railway. — *a*), *b*), *c*) and *d*) No.

Furness Railway. — *a*), *b*) *c*) and *d*) No.

Great Central Railway. — *b*) Yes through all vehicles. — *d*) No.

Great Western Railway. — *a*) No. — *b*) Yes. — *c*) Usually one trailer hauled or propelled by motor car. Electrical communication. — *d*) No.

Lancashire & Yorkshire Railway. — *a*) No. — *b*) Continuous brakes are used on rail coach and all other coaches that are hauled. — *c*) Intercommunication can be made with the rail motor coach and the specially designed trailer coach. — *d*) No.

London & North Western Railway. — *b*) Our cars are fitted with the continuous brake. — *d*) No.

London, Brighton & South Coast Railway. — No.

Midland Railway. — *b*) Yes; we have vacuum brake communication with all trailers. — *d*) No liquid fuel or automatic feeding used.

North Eastern Railway. — See appendix II.

Port Talbot Railway. — *a*) Yes. — *b*) No. — *d*) No.

South Eastern & Chatham Railway. — *a*) Driver and stoker are employed. — *b*) We use continuous brakes upon motor cars and also where they haul trailer cars. — *c*) There is no intercommunication with the car hauled. All cars are hauled not pushed. — *d*) No.

Taff Vale Railway. — *a*) The starting, stopping, operating the reversing lever and attending to the boiler is in the hands of the assistant motorman, but the look-out for road-signals and the signal for starting and stopping is in the hands of the motorman. — *b*) All cars fitted with continuous brakes. — *c*) No intercommunication with the first car hauled. — *d*) No.

Dublin & South Eastern Railway. — *a*) No. — *b*) Continuous brakes on engine and all cars. — *c*) No intercommunication with cars. — *d*) No.

Great Northern Railway (Ireland). — *a*) No. — *b*) Yes. — *c*) No intercommunication. — *d*) No.

Central South African Railways. — See answer to No. 2.

South Australian Government Railways. — *a*) No.

Great Indian Peninsula Railway. — *a*) No. — *b*) Automatic Vacuum Brake on all. — *c*) No.

Madras & Southern Mahratta Railway. — *b*) Yes. — *c*) No. — *d*) No.

North Western State Railway of India. — *d*) Coal.

QUESTION **6.** — *Profile of line over which cars work giving distances between stations, gradients and radius of curves.*

Alexandra (Newport) Docks & Railway. — See fig. 41.

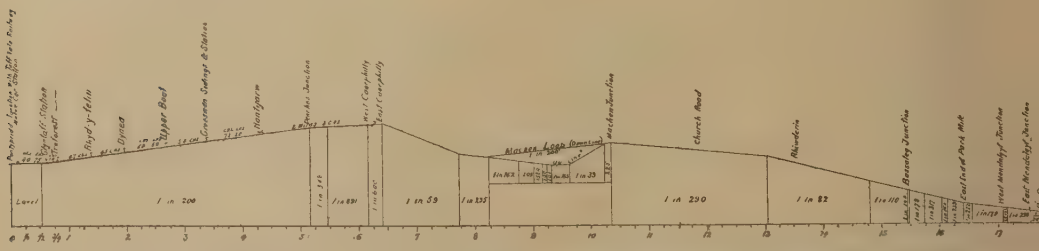

Fig. 41. — Alexandra (Newport) Docks & Railway Company. — Section of railway from Pontypridd Junction to Alexandra

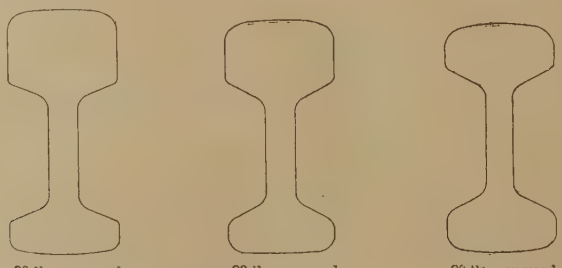

90 lb. per yard. 83 lb. per yard. 80 lb. per yard.

Fig. 54. — Midland Railway. — Gradients.

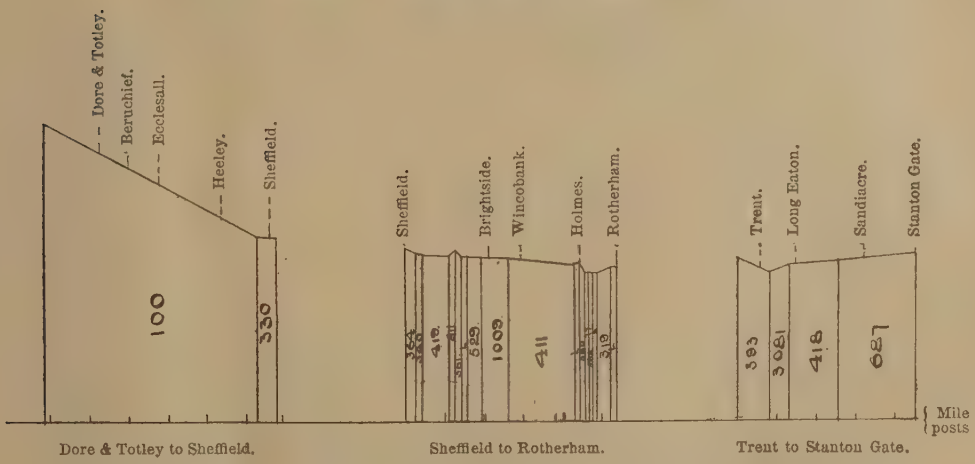

Fig. 55. — Midland Railway. — Gradients.

QUESTION 7. — *Daily services performed by cars : a) Stations at each end and mileage. — b) If services divided into two stages worked by different cars.*

Alexandra (Newport) Docks & Railway. — *a*) Fourteen journeys to and from Pontypridd. Pontypridd and Caerphilly. Mileage corresponding to each run 6 ½ miles. The cars run alternate days. Total running per day 182 miles. — *b*) No.

Furness Railway. — *a*) Coniston to Foxfield 10 miles. Three intermediate stops. Eight trips (single) Foxfield to Broughton and back 2 miles. Total mileage per car per day 82 miles.

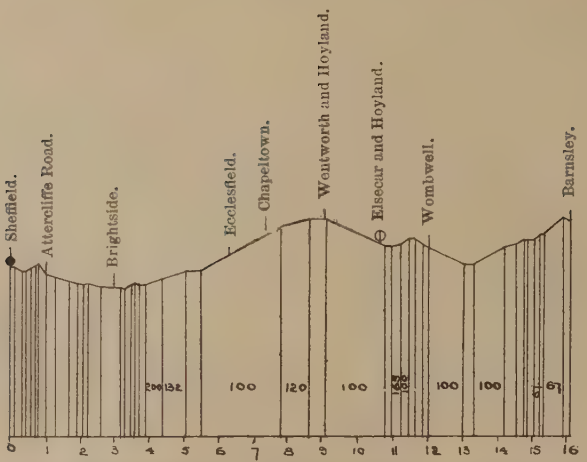

Fig. 56. — Midland Railway. — Sheffield to Barnsley. — 16 miles 11 chains.

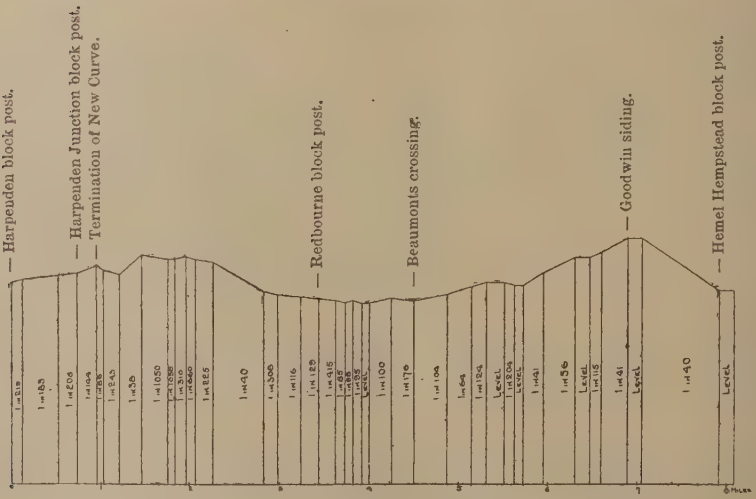

Fig. 57. — Midland Railway. — Gradients from Harpenden to Hemel Hempstead.

Great Central Railway. — *a*) See time-tables. — *b*) No.

Great Western Railway. — *a*) See details. Time-tables. — *b*) One stage only. Practically only one type of car as far as design of engine is concerned. Maximum daily working of one car at present is 220 miles.

Lancashire & Yorkshire Railway. — *a*) Separate statement. — *b*) No.

ton-in-Ashfield
Sutton Junction.

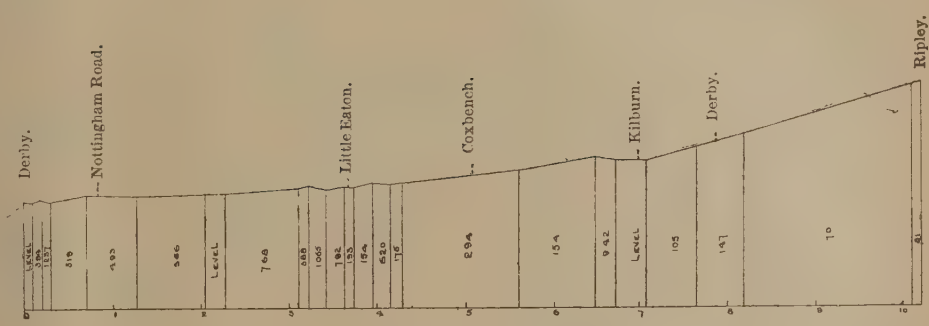

Fig. 60. — Derby and Ripley.

Figs. 58 to 60. — Midland Railway. — Gradients.

London & North Western Railway. — *a*) See time-tables. — *b*) No.

London, Brighton & South Coast Railway. — No services are divided. The maximum daily working on any service is 292 miles.

Midland Railway. — *a*) See time-table.

North Staffordshire Railway. — *a*) General total of 1,000 miles per week for three cars. Maximum number of miles worked in one day 89 miles. — *b*) No.

North Eastern Railway. — *a*) Selby and Wistow and return four times daily. Distance, 5 1/4 miles. Total, 42 miles. Petrol Electric Autocars. Selby and York return. One journey daily. Distance, 28 miles. Petrol Electric Automotor car. Total mileage per day, 70.

Port Talbot Railway. — *a*) 105 miles per day.

Rhymney Railway. — *a*) One car makes eight journeys of 4 1/2 miles each. Senghenydd and Caerphilly, and four journeys of 8 1/2 miles each Senghenydd and Machen. Total, 70 miles. The other car makes eight journeys of 10 miles each Rhymney and Ystrad Mynach, and two journeys of 11 miles each, Merthyr and Ystrad Mynach. Total, 102 miles. Total of both cars per day 172 miles. — *b*) No.

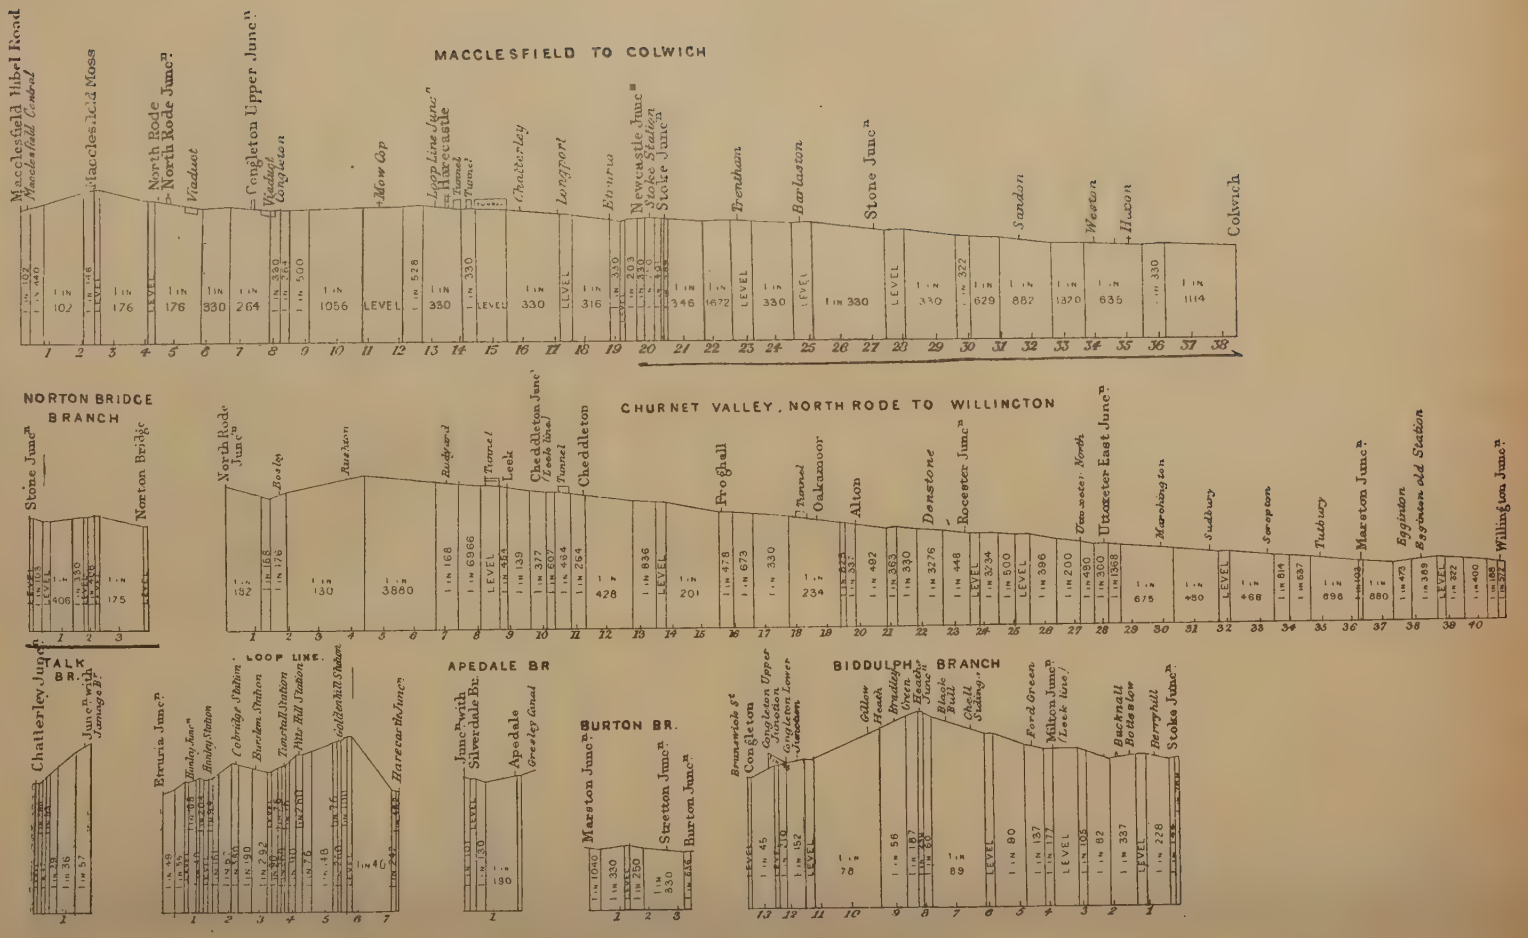

Fig. 61. — North Staffordshire Railway. — Diagram of gradients. [Lines on which run are underlined by a large line.

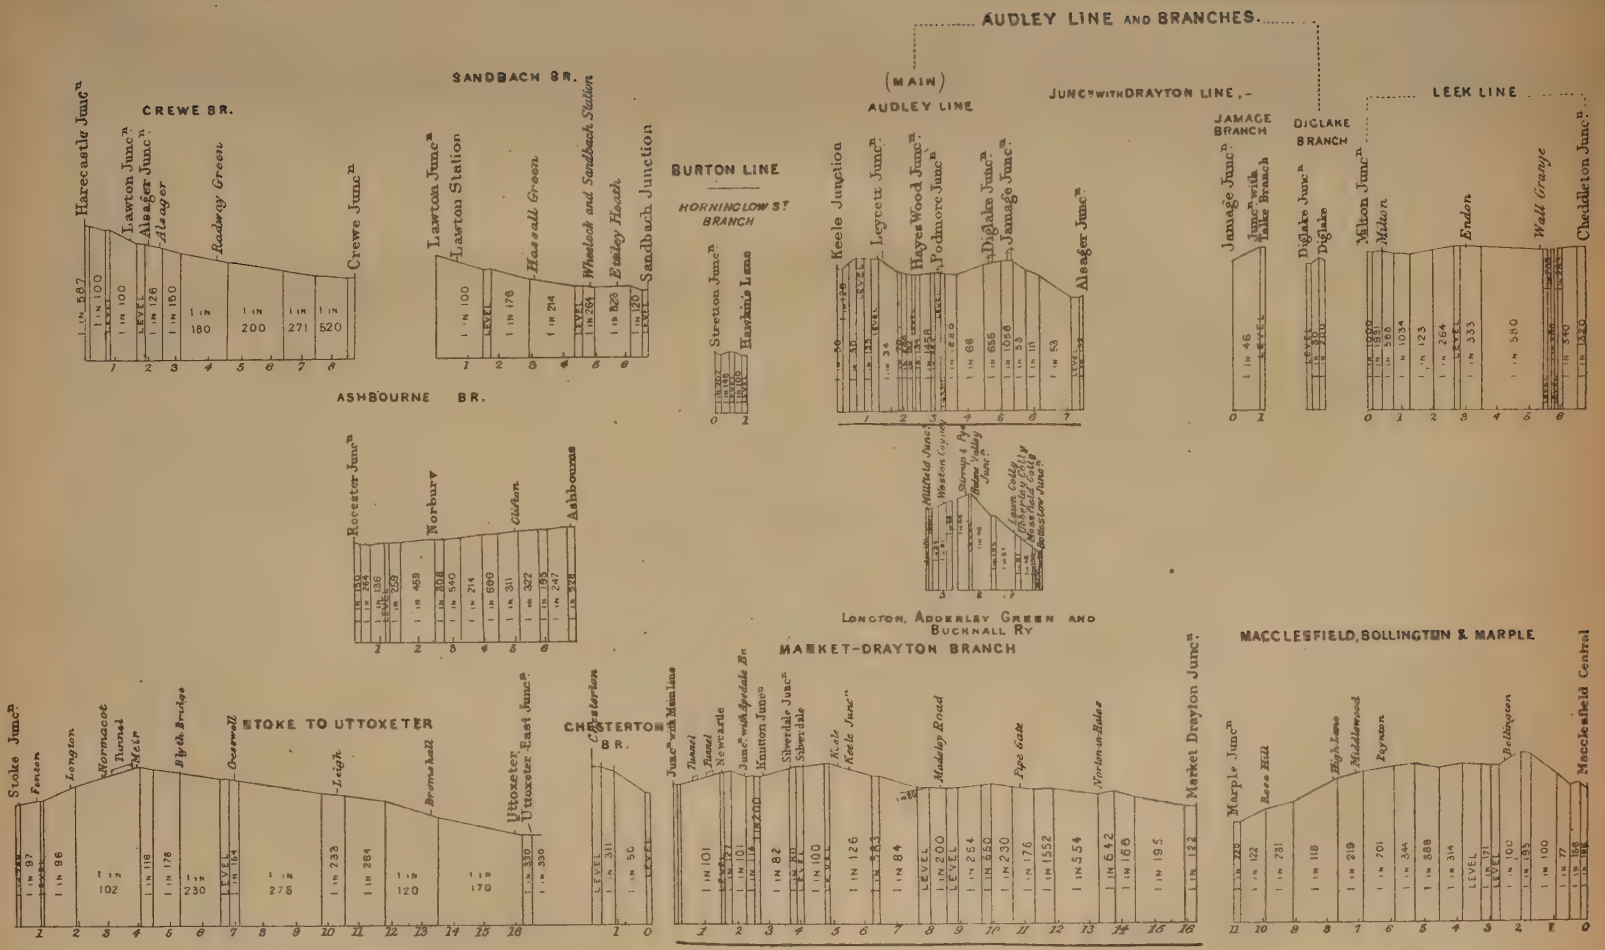

Fig. 62. — North Staffordshire Railway. (*Continued.*) — Diagram of gradients. Lines on which run are underlined by a large line.

Fig. 73. — Madras & Southern Mahratta Railway.

Taff Vale Railway. — *a*) For particulars of services see time-tables. The runs between terminal points vary from 4 miles 29 chains to 21 miles 32 chains. The aggregate miles per day between terminal points range from 42 $^{3}/_{4}$ miles to 148 $^{3}/_{4}$ miles. Total miles per day run by all cars, 1,059.

Central South African Railway. — *a*) Class 1 : runs on the Pretoria Suburban Service, the longest runs being to Hatherley, 12 miles, to the East, and Pretoria North, 9 miles to the North. The total daily mileage is about 125 miles. — Class 2 : runs on the Germiston Suburban Service to Elsburg, 5 miles to the south, and Rietfontein 5 miles to the west of that place. The total daily mileage is about 125 miles.

South Australian Government Railways. — *a*) These cars do not run a daily service. Average run about 100 miles per trip.

Great Indian Peninsula Railway. — *a*) Average 40 miles per day.

Madras & Southern Mahratta Railway. — *b*) No.

Question 8. — *a) Average weight empty.* — *b) Average weight when at work.* — *c) Number of axles of the cars.*

Alexandra (Newport) Docks and Railway. — *a*) No. 1 : 36 tons; No. 2 : 39 tons. — *b*) No. 1 : 40 tons; No. 2 : 43 tons. — *c*) Number of axles, 4.

Furness Railway. — *a*) Total weight full car and trailer, 56 tons 7 cwt. — *c*) Number of axles, 6.

Lancashire & Yorkshire Railway. — *a*) Weight of trailer coach empty, 26 tons 4 cwt. — *b*) With full complement of passengers and one ton of luggage, 31 tons 5 cwt. — *c*) Four axles.

London Brighton & South Coast Railway.

Class 1 :				
Engine.	Empty.	22	0	—
	Loaded	27	2	—
Coach	Empty.	23	15	—
	Loaded	28	0	—
Total	Empty.	45	15	—
	Loaded	55	2	—
Class 2 :				
Engine and car.	Empty.	30	3	—
	Loaded	38	7	—
Class 3 :				
Engine and car.	Empty.	14	0	—
	Loaded	17	10	—
Class 4 :				
Engine and car.	Empty.	17	4	—
	Loaded	20	14	—

North Staffordshire Railway. — *b*) Weight in working order, 32 tons 9 cwt. — *c*) Two axles on trailer car.

North Eastern Railway. — *a*) 35 tons. — *b*) 38 tons. — *c*) Only one self contained car is run.

Port Talbot Railway. — *c*) Four axles.

Rhymney Railway. — *a*) 55 tons 2 cwt. — *b*) 59 tons 4 cwt. 2 qrs. — *c*) Nine axles usually hauled by motor car.

South Eastern & Chatham Railway. — *a*) Trailing carriages average 12 tons empty. — *c*) Three axles.

Taff Vale Railway. — *a*) Large Car, 40 tons 5 cwt. — *a*) Small Car, 31 tons 19 cwt. — *b*) Large Car, 44 tons 11 cwt. — *b*) Small Car, 35 tons 14 cwt.

Great Northern Railway (Ireland). — *a*) About 22 tons. — *c*) Four axles.

Central South African Railway. — *a*) Class No. 1 : 40 tons; Class No. 2 : 39 $^1/_4$ tons. — *b*) Class No. 1 : 44 $^3/_4$ tons; Class No. 2 : 47 $^1/_2$ tons.

Great Indian Peninsula Railway. — *a*) Engine end 24 tons. — *b*) Engine end 27 tons.

Madras & Southern Mahratta Railway. — *a*) 11 tons 10 cwt. — *b*) 14 tons 10 cwt. — *c*) Two axles.

North Western State Railway of India. — *b*) 43 tons (without passengers). — *c*) 4 axles.

QUESTION 9. — *Average and maximum number of hauling cars and total weight inclusive of passengers luggage, etc.*

Furness Railway. — Maximum number of cars hauled, 3. Total weight including auto. motor, 72 tons 7 cwt.

Great Western Railway. — Car including passengers and luggage 49 tons approximately.

Lancashire & Yorkshire Railway. — One. Total weight in working order but without passengers is 49 tons 10 cwt. 2 qrs.

Midland Railway. — Class 1 : 1 haulage car. Weight without trailer (including passengers), 45 tons 16 cwt.; Weight with trailer (including passengers), 67 tons 14 cwt. — Class 2 : No trailers; 64 tons. Trailers might be any two vehicles of ordinary rolling stock. — Class 3 : No trailers; 85 tons 8 cwt. Trailers might be any two vehicles of ordinary rolling stock.

North Staffordshire Railway. — Only one trailing car is generally used, but an additional vehicle has been hauled on level road. Weight of one trailing car (loaded) 12 tons.

North Eastern Railway. — Each journey 1 car, weight 38 tons.

Rhymney Railway. — The average and maximum number of hauling cars are three, 6 wheels. Coaches weight when empty 37 tons 10 cwt., weight when at work 48 tons 15 cwt. No luggage.

Dublin & South Eastern Railway. — Maximum, 3. Average, 2. Maximum, 83 tons. Average, 67 tons.

Central South African Railways. — See No. 1 of this section.

Madras & Southern Mahratta Railway. — One trailer for passenger only.

North Western State Railway of India. — One bogie hauled. 24 tons light.

QUESTION 10. — *a) Number of cars owned. — b) Date of building first and last.— c) Number of units effectively employed in the daily service. — d) Average number of units stopped for washings, etc. — e) Annual mileage per motor car.*

Alexandra (Newport) Docks and Railway. — *a)* 2. — *b)* First in 1904, second in 1905. — *c)* 8. — *d)* One per week. — *e)* Mileage run in 1907 : No. 1 car, 20,321 miles; No. 2 car, 35.396 miles.

Furness Railway. — *a)* Only one in service. — *b)* 1905. — *d)* Replaced by locomotive when stopped for washing out, repairs, etc.

Great Central Railway. — *a)* 3 self contained, 2 separate.

Great Western Railway. — *a)* 100. — *c)* 79 daily employed.

Lancashire & Yorkshire Railway. — *a)* 2 cars with boilers of the double barrel type. — 6 cars with boilers of the locomotive type. — 7 cars with boilers of the locomotive type and

designed to couple up to specially designed trailer cars. — *b*) First car March 1905. Last car March 1907. — *c*) Annual mileage 33,551 miles.

London & North Western Railway. — *a*) 6 cars and 7 engines. — *b*) First car August 1905, last car April 1906.

London Brighton & South Coast Railway. — *a*) Class 1, 20; class 2, 2; class 3, 1; class 4, 1. — *b*) Class 1 : first car June 1905; last car April 1909; class 2 : Both built August 1905; class 3 : July 1905; class 4 : July 1905 converted to petro-electric, September 1908.

Midland Railway. — *a*) Class 1, 2; class 2, 4; class 3, 7. — *b*) Class 1 : July 1904; class 2 : February 1906; class 3 : July 1908. — *c*) Class 2 : Number actually running from time they commenced running, 2; class 3 : Number actually running from time they commenced running, 5; *e*) Class 1 : Average mileage per car for first four years 8,240 miles; class 2 : Average annual mileage 11,516 miles; class 3 : No figures for year. Average per week in July 1908, 475 miles per car.

North Staffordshire Railway. — *a*) Three. — *b*) Two in May 1905. 1 May 1906

North Eastern Railway. — *a*) Two. — *b*) 1904. — *c*) One. — *d*) One. — *e*) 10,920 miles.

Port Talbot Railway. — *a*) One only.

Rhymney Railway. — *a*) Two. — *b*) 1907. — *c*) Cars are in use daily. — *d*) Washing and cleaning is done at night time, and when in for repairs, trains hauled by locomotives work the service. — *e*) Annual mileage per car 13,326.

South Eastern & Chatham Railway. — *a*) Eight. — *b*) First in 1905 and last in 1906.

Taff Vale Railway. — *a*) Sixteen motor cars and two spare engines. — *b*) December 1903. June 1906. — *c*) Average mileage 19,922.

Dublin & South Eastern Railway. — *a*) Two. — *b*) 1906. — *d*) Stopped for washing out etc. on Sundays. — *e*) 16,956 miles.

Central South African Railways. — *a*) Two. — *b*) April 1906 and May 1907.

South Australian Government Railways. — *a*) Two. — *b*) 1906.

Madras & Southern Mahratta Railway. — *a*) Three. — *b*) 1907. — *c*) All cars have hitherto been at work.

North Western State Railway of India. — *a*) Only one car on system.

QUESTION 11. — *" For the small locomotives referred in questions 1 to 15 if you have such you ave asked to reply to questions 6 to 10 as above in as much as this may be of interest in regard to comparison with the automotor cars ".*

No information received in reply to this question beyond what is given in answer to other questions.

QUESTION 12. — *a*) *Whether motor car services are worked to time-table.* — *b*) *If considered as trains.* — *c*) *In the event of an extraordinary rush of passengers, do you put on supplementary trains worked by another automotor car or by a locomotive, or merely start a locomotive with a larger number of cars.* — *d*) *Are motor cars run to fixed times in connection with other trains or have they an exclusive character of local service.*

Alexandra (Newport) Docks and Railway. — *a*) Yes. — *b*) Yes, but when possible, additional accommodation is provided. — *c*) Yes. — *d*) The have an exclusive character of local service.

Furness Railway. — *a*) No. — *b*) No. — *c*) Extra vehicles are put on to car. — *d*) Run in connection with other trains.

Great Central Railway. — *a*) To time table only. — *b*) and *c*) Yes, strengthened when necessary if running engine first. — *d*) Same as other trains.

Great Western Railway. — *a*) Yes. — *b*) Yes, but seats not limited. When it is known there will be abnormal traffic beyond the capacity of a car and trailer, a locomotive and train or an auto-engine and trailers work the service. — *c*) In the case of a rush at short notice, the following alternatives are followed, as circumstances permit : 1° supplementary train run either by locomotive and train or automotor car; 2° locomotive and train substituted for automotor car; 3° additional trips by automotor car. — *d*) Cars submitted to fixed times with other trains.

Lancashire & Yorkshire Railway. — *a*) Yes. — *b*) No. They are considered as trains with only third class accommodation; in cases of extra traffic, a trailer coach is attached to the rail coach. — *c*) But when it is known that at a given time the traffic will exceed the capacity of the rail motor, it is replaced by an ordinary train. — *d*) The rail motor services are worked to fixed times with other trains.

London & North Western Railway. — *a*) Yes. — *b*) Yes. — *c*) We have occasionally found it necessary to run supplementary trains where the 6 cars are working. — *d*) They are exclusively local service, but have connection with main line trains.

London, Brighton & South Coast Railway. — *a*) Yes. — *c*) Such emergencies are foreseen and special ordinary trains are put on. Where the one car is likely to be overcrowded, the second is attached from ordinary stock but not more than one extra. — *d*) The motor car runs are scheduled with other trains and run with perfect punctuality to coincide with ordinary traffic.

Midland Railway. — *a*) Time shewn in time-tables and distinguished there as motor trains. — *b*) They are not trains with a limited number of seats. — *c*) Various devices have been tried when the traffic has been abnormally great, such as coupling two automotors of Class 1 together with two trailers and alternating the services of this train with a train hauled by an ordinary locomotive. Now, however, Class 1 is little used and then at places where no abnormal rush is to be expected. With Classes 2 and 3, two more coaches can be added to take the increased traffic. — *d*) These automotor trains do not run exclusively on any line but alternate with ordinary passenger trains and goods traffic, the times being fixed for each type in working and passenger timetables.

North Staffordshire Railway. — *a*) Yes advertised in time-tables as rail motors. — *b*) Yes. — *d*) In some cases the rail motors take the place of trains and otherwise run between ordinary trains.

North Eastern Railway. — *a*) Yes. — *b*) Yes. — *c*) Second auto car run if found necessary. — *d*) Local service purely except the run to York, which is run to fixed times and with other trains.

Port Talbot Railway. — *b*) No. — *d*) Fixed times.

Rhymney Railway. — *a*) Yes. — *b*) No. — *c*) Yes, if the automotor car is unable to take sufficient cars to accommodate the passengers, a locomotive with a larger number of cars to form the service. — *d*) Fixed times.

Taff Vale Railway. — *a*) Yes. — *b*) No. — *c*) Sometimes the cars are duplicated, at other time a relief train is provided. — *d*) Yes.

Dublin & South Eastern Railway. — *a*) Yes. — *b*) Yes. — *c*) Ordinary train put on in lieu of motor train. — *d*) Ordinary local service.

Central South African Railways. — *a*) The services of these cars are scheduled in the public timetable as in the case of the ordinary local suburban trains. The seating accommodation is limited, but on occasions, passengers are willing to stand, the average journey being very short.

South Australian Government Railways. — *a*) and *b*) Yes these cars are shewn in the time-tables and are considered as trains in every respect. — *c*) In the event of a rush of passengers. A train would have to be provided.

Great Indian Peninsula Railways. — *a*) Public notices issued. — *b*) Yes. — *c*) We run extra trains. — *d*) Fixed times.

Madras & Southern Mahratta Railway. — *a*) Yes, if there is no accommodation passengers take following ordinary trains. There is a convenient train service on the section. — *c*) If there is sufficient number of passengers, a special is arranged to convey them irrespective of ordinary trains. — *d*) Fixed times.

Question **13**. — *a*) *Is your motor car service for secondary lines limited to runs sandwiched between existing passenger trains.* — *b*) *Whether motor cars are used to meet whole passenger service on certain sections of the railway.* — *c*) *Has this course necessitated running goods trains where mixed trains were formerly run for the conveyance of cattle, etc.*

Furness Railway. — *a*) No. — *b*) No.

Great Central Railway. — *a*) Yes.

Great Western Railway. — *a*) Yes. — *b*) Branches where there are both passenger and goods trains to be dealt with are worked by auto engines, the trailer being disconnected when working the goods trips. — *c*) An automotor car will deal with limited horse milk and cattle traffic (vacuum fitted vehicles) in special cases.

Lancashire & Yorkshire Railway. — *a*) No, in most cases they have entirely superseded the ordinary trains. — *b*) Yes. — *c*) Marchandise and cattle were carried by separate goods train previous to the advent of rail motors, and are still so carried.

London & North Western Railway. — *a*) In four cases, yes, in two cases the whole of the passenger train service is worked by the cars. — *b*) Yes, the cars are used exclusively on two

services. — *c*) The goods services are provided by ordinary goods trains, independently of the passenger car service.

London, Brighton & South Coast Railway. — *a*) In most cases-yes. — *b* and *c*) On one branch, Brighton to Kemptown, the service is worked exclusively by motor trailer car. Goods, cattle, and express goods carried, shunted, etc., by ordinary locomotive and stock.

Midland Railway. — *b*) Nothing has been done in the way of complete services as yet.

North Staffordshire Railway. — *c*) No.

North Eastern Railway. — *a*) No, at present time complete service on one branch line except for the one run to York and back which is run between ordinary trains hauled by locomotives. — *b*) Yes, the service is on a line of this class. — *c*) By the ordinary goods train.

Port Talbot Railway. — *a*) Run as ordinary passenger train.

Rhymney Railway. — *a*) Yes. — *b*) On one branch the complete service during the day time is worked by automotor car. — *c*) No. Vans are attached in the rear of the automotor car as found necessary.

Taff Vale Railway. — *a*) Yes. — *b*) No.

Dublin & South Eastern Railway. — *a*) No. — *b*) Yes. — *c*) No, passenger line only.

Central South African Railways — *a*) Yes. — *b*) The question of using these cars exclusively to deal with branch line passenger traffic has not been considered to date. At present the service is run in connection with and sandwiched between, the ordinary passenger and mixed traffic service.

South Australian Government Railways, — *b*) It is not intended to adopt these vehicles to deal solely with the passenger traffic. — *c*) As the regular goods traffic does not warrant the running of mixed trains daily the cars are being used to deal with the light passenger and mail traffic on alternate days.

Great Indian Peninsula Railway. — *a*) Yes, sandwiched between existing trains. — *b*) No but the matter is under consideration. The motor only becomes economical when there is more work than one engine can do.

Madras & Southern Mahratta Railway. — *a*) No. — *b*) Yes. — *c*) Carried by goods train.

QUESTION 14. — *Is it intended to extend the use of motor cars to meet the competition of tramways or simply to improve existing services where short and frequent stops are necessary.*

Furness Railway. — No.

Great Western Railway. — No additional services proposed at present.

Lancashire & Yorkshire Railway. — No.

London & North Western Railway. — There is no present intention of extending the use of these cars.

London, Brighton & South Coast Railway. — The system of trailer cars is likely to be extended where ever full-sized stock can be superseded for picking up a few passengers and where "halts" can be profitably made, to gather in travellers who would otherwise journey by carrier, road motor, or other competitive form of conveyance. The motor services already enable this class of traveller, and those from unimportant stations to join trains at the chief stopping places conveniently.

Midland Railway. — Our automotor train working is practically confined to local branch traffic ant it is to work this class of traffic at moderate expense that this system has been originated.

North Staffordshire Railway. — No.

North Eastern Railway. — No.

Port Talbot Railway. — Sole object in adopting motor car was economy.

Rhymney Railway. — The motor services will be extended to short branches as they are opened for the purpose of feeding the main line trains.

Taff Vale Railway. — Uncertain.

Dublin & South Eastern Railway. — Yes.

Central South African Railways. — The two motor coaches at present running on our lines are giving satisfaction, in that they provide transportation facilities to the public whose requirements in this direction are not other wise catered for. In inaugurating the services, the object aimed at was not competition with other methods of transport which on the routes taken is non-existent. The motor train service is arranged so as to give the suburban public facilities for joining long distance trains at Pretoria and Germiston. The headquarters of the respective services and to provide travelling facilities for that section of the public who reside along the railway. The question of using this type of vehicle exclusively instead of light passenger trains for branch line service has been considered, but so for no practical application of the idea has been made.

South Australian Government Railways. — No.

Great Indian Peninsula Railway. — As funds permit, we propose to extend our programme. It is possible we may use the cars to feed fast trains and also distribute from fast trains, but our first object will be to provide a more efficient service on short branches.

Madras & Southern Mahratta Railway. — No.

QUESTION 15. — *Is it intended to utilise motor cars on certain sections, as a temporary measure, to ascertain whether the result would justify the running of regular passenger trains.*

Alexandra (Newport) Docks and Railway. — No.

Furness Railway. — No.

Great Western Railway. — The introduction of automotor cars was to give an increased frequency at a moderate expense and to tap new sources of traffic by stopping at suitable intermediate points between stations. No cases of car services being converted into train services, nor of motor service being discontinued.

Lancashire & Yorkshire Railway. — No.

London & North Western Railway. — No.

Midland Railway. — No.

North Staffordshire Railway. — No.

North Eastern Railway. — No.

Taff Vale Railway. — This aspect of the question has not been considered.

Dublin & South Eastern Railway. — No.

Central South African Railways. — The services provided so far have only been on routes where it was known that this class of traffic was offering, and the cars have not been used experimentally as creators of traffic to date.

South Australian Government Railways. — No.

Great Indian Peninsula Railway. — This has been thought of but not given effect to.

Madras & Southern Mahratta Railway. — Yes.

QUESTION 16. — *Are motor cars allotted to sundry local journeys on sections where no trains are run on Sundays, or at Holiday times; and do you use such days for the cleaning of the cars.*

Alexandra (Newport) Docks and Railway. — Yes.

Furness Railway. — No.

Great Western Railway. — No.

Lancashire & Yorkshire Railway. — No.

London & North Western Railway. — These cars are run during the six working days of the week like other local passenger trains only one regular trip is made on Sundays from Walsall to Hednesford and back. The washing out etc. is done during the week nights when the cars are not in service.

Midland Railway. — This has been our general practice.

North Staffordshire Railway. — Yes.

North Eastern Railway. — Allotted to sundry local journeys on sections where no trains are run on Sundays.

Rhymney Railway. — The cars are not booked to run on Sundays and public holidays. Yes.

Taff Vale Railway. — Some services are run with motor cars on Sundays and others with trains, and we wash out and do shed repairs to as many as can be dealt with on Sunday.

Dublin & South Eastern Railway. — No.

Central South African Railways. — The journeys allotted to these cars are arranged to suit the needs of the public and exigencies of the heavier traffic. There is a fixed service for all week-days and another for Sundays, and these are not altered for special occasions. As the cars run on a day service only, washing out and ordinary light repairs can be effected at night.

South Australian Government Railways. — Apart from the ordinary journeys, these cars may be hired for picnic parties, etc. As the cars do not run a daily service, the off days allow sufficient time for repairs, etc.

Great Indian Peninsula Railway. — Motor car does run on Sundays. The cars run when the traffic is lightest, *i. e.* in the middle of the day.

QUESTION 17. — *Are motor cars stabled in the locomotive sheds or are separate sheds provided, worked by a special staff.*

Alexandra (Newport) Docks and Railway. — We have a separate shed for the cars. No special staff employed.

Furness Railway. — Stored in carriage stock shed on station siding. Same staff used as for locomotives.

Great Western Railway. — Separate sheds in two cases only. Same staffs as for locomotives.

Lancashire & Yorkshire Railway. — Yes. The rail motor is maintained by the engine shed staff. The carriage is maintained by the carriage department staff.

London & North Western Railway. — They are kept in the same sheds as our locomotives, and are attended to by the ordinary staff.

London, Brighton & South Coast Railway. — Class 1 : The engines are detached from trailer car and make shed as ordinary. The car is sided with regular stock. — Class 2 : Engines and cars shed in ordinary steam shed. — Classes 3 and 4 : Stand at end of dock platforms at Brighton Station only.

Midland Railway. — No special sheds are provided.

North Staffordshire Railway. — Rail motor cars are stabled in a separate shed but same staff look after these cars that attend to the locomotives, the rail motor shed being alongside the running shed.

North Eastern Railway. — No. Stood in open and dealt with by special staff.

Rhymney Railway. — Yes. By the same staff.

South Eastern & Chatham Railway. — Automotor cars as a rule are kept in the same sheds as the locomotives.

Taff Vale Railway. — Yes. Worked by the same staff.

Dublin & South Eastern Railway. — Locomotives separated for stabling.

Great Northern Railway (Ireland). — Separate shed and a special staff.

Central South African Railways. — These cars are stored in the same sheds as the Main Line Locomotives, and are dependent on the ordinary running shed, staff for up-keep and light repairs.

South Australian Government Railways. — The same staff attend to the motor cars as to the locomotives, but they are not stabled in the same sheds.

Great Indian Peninsula Railway. — Usually stabled in locomotive shed.

Madras & Southern Mahratta Railway. — Yes. Same staff used as for locomotives (no separate shed).

North Western State Railway of India. — Only one car on the system. Car kept in locomotive shed. No special staff kept for it.

Section III. — **Technical and economical results.**

Question **1.** — *What is the maximum distance run in regular service without taking water or fuel.*

Furness Railway. — With stopping train 20 miles.

Great Western Railway. — About 30 miles. Water capacity not provided for longer distances.

Lancashire & Yorkshire Railway. — Distance run without stopping. Double barrel type : For fuel, 50 miles ; for water, 38 miles. — Locomotive boiler type : For fuel, 100 miles ; for water, 38 miles.

London & North Western Railway. — 20 miles.

London, Brighton & South Coast Railway. — The steam cars can run a distance totalling up to 50 miles on coal and water carried. Circumstances allow of the maximum run between replenishments being not more than 22 miles.

Midland Railway. — With one of our automotors the journey from Derby to London has been run without taking on any extra coal and with two extra supplies of water only. Distance 127 miles.

North Staffordshire Railway. — From 14 to 20 miles with the supply of water carried by our cars, according to the part of the line being worked over, *i. e.* level or otherwise.

North Eastern Railway. — 240 miles.

Port Talbot Railway. — 35 to 40 miles without taking water. 125 miles without taking coal.

Rhymney Railway. — The motors run on an average 650 miles per week.

Taff Vale Railway. — 100 to 130 miles per day for coal. Water about 40 miles.

Dublin & South Eastern Railway. — 70 miles.

Central South African Railways. — Class 1 : The coal bunker on the engine of this car has a capacity of 1 1/2 tons sufficient for a 120 miles run, and 550 gallons of water are carried in the side tanks sufficient for 40 miles.

South Australian Government Railways. — Class 2 : The coal bunker on the engine of this car has a capacity of 1 1/8 tons sufficient for a run of 100 miles and 500 gallons of water are carried in the side tanks sufficient for a 35 mile run.

South Australian Government Railways. — These cars carry sufficient coal and water for a journey of from 25 to 30 miles.

Great Indian Peninsula Railway. — A 20 mile run with 6 cwt. of coal and 350 gallons of water.

Madras & Southern Mahratta Railway. — 25 miles.

North Western State Railway of India. — 30 miles approximately.

QUESTION 2. — *Does it take longer to "water" these cars than an ordinary locomotive and have you found it necessary to adopt special appliances for this purpose?*

Alexandra (Newport) Docks and Railway. — No. We make use of the same hydraulic cranes for the cars and locomotives.

Furness Railway. — Slightly longer time. Same water crane as used for locomotives.

Great Western Railway. — No. Same water arrangements as locomotives.

Lancashire & Yorkshire Railway. — Ordinary locomotive hydrants will suit, but special hydrants have been fixed for rail motors at starting places in order to save shunting time, etc.

London & North Western Railway. — We do not take in water at intermediate stations. The boiler and tanks are filled up at the terminal stations by means of a hose pipe coupled to a water hydrant.

London Brighton & South Coast Railway. — The engines feed from the standard cranes.

Midland Railway. — Special tundish carried on car to receive water from feed pipe but otherwise no special arrangement, *i. e.* hydrants or cranes.

North Staffordshire Railway. — No the tank lids are of ordinary dimensions so that a water column hose bag can be used as on locomotives.

North Eastern Railway. — Water supply sufficient for one week.

Port Talbot Railway. — No special fittings used.

Rhymney Railway. — The same hydrants are in use with the motors as with engines. We find the motors are no longer taking water than the engines.

Taff Vale Railway. — About the same time. Yes — but it was to facilitate dispatch of traffic working and the cranes used by the locomotives are made use of.

Dublin & South Eastern Railway. — No.

Great Northern Railway (Ireland). — No.

Central South African Railways. — The water tanks on the locomotives of these cars are filled from the standard locomotive water colums.

South Australian Government Railways. — About the same times are allowed as for the locomotives and the same appliances used.

Great Indian Peninsula Railway. — We use the ordinary cranes but had to cu a larger hole in cab plate to allow hose to enter. Filling does not take longer than other tank engines.

Madras & Southern Mahratta Railway. — No.

North Western State Railway of India. — No watering at intermediate stations.

QUESTION 3. — *What are the most difficult performances that have been carried out as regards effort af traction, working of boilers, speed attained over varying grades, etc., and maximum speed and acceleration speed on level.*

Alexandra (Newport) Docks and Railway. — No records.

Furness Railway. — The most difficult performance is the service on which the car is now running; given in II, Nos. 7, 8 and 9.

Great Western Railway. — No special tests made. Ordinary acceleration on level 30 miles per hour in 30 seconds.

Lancashire & Yorkshire Railway. — The most difficult performance is when a car is being hauled from Bury to Holcombe Brook. Average gradient 1 in 50. Length of journey 3 miles 408 yards. Maximum gradient, 1 in 40. Length of journey for maximum gradient, ½ mile. Maximum journey without stop, 3 miles 352 yards. Average booked speed for same 8 minutes. Maximum speed on level 40 miles per hour.

London & North Western Railway. — See gradient sheets shewing the gradients on the Prestatyn and Dyserth Branch which are the steepest we have to work over with these cars. Prestatyn to Rhyl, 28 miles per hour.

Midland Railway. — A speed of 70 miles per hour has been attained on a down gradient of 1 in 300 but 60 miles per hour can be attained on level road : these results are obtained with no trailers. 45 miles per hour has been reached with 4 10-ton guard's brakes on level. Maximum journey without stops has been 40 miles done in 55 minutes with the car only, no trailers. With 12- loaded wagons (10 tons each) have been pushed up a gradient of 1 in 120 in the ordinary through goods time.

North Staffordshire Railway. — Our journeys are short ones, but you will see by the profile that gradients of 1 in 34, 1 in 50, 1 in 66, 1 in 82, etc., are negociated but the engine has to be thrashed in some cases to keep time. About 40 miles per hour.

North Eastern Railway. — Average 28 miles per hour. Maximum 35 miles per hour. Full speed in 2 3/4 minutes.

Port Talbot Railway. — Never tried more than one trailer.

Rhymney Railway. — 40 miles per hour.

South Eastern & Chatham Railway. — 40 miles per hour. 30 miles per hour in half a minute.

Taff Vale Railway. — Starting on gradients of 1 in 40. Boiler gives no trouble. 1 in 40 varying 1/2 mile to 1 mile. 30 miles per hour. 30 miles per hour in 30 seconds.

Dublin & South Eastern Railway. — Service is 6 miles run in 20 minutes with six intermediate stops hauling 3 cars weighing 53 tons. Line practically level. Average speed 18 miles per hour including stops. A speed of 38 miles is attained between stations. 35 miles per hour. 20 miles per hour in 30 seconds.

Central South African Railways. — No special experiments have been made with either of these cars as regards speed load or stability. Number 1 car is much steadier in running than No. 2 car and affords more comfort for passengers. No. 2 having the engine and coach on the one framework makes the whole vehicle to ride very roughly, consequently No. 1 car can be run at a higher speed than No. 2 car without excessive vibration or rolling.

South Australian Government Railways. — The heaviest work these motors are called upon to do is in running over the length of line shewn on figure 40 at an average speed of 17 miles per hour. Maximum speed on the level 31 miles per hour.

North Western State Railway of India. — 44 miles an hour working light on trial trip.

QUESTION 4. — *What difficulties, if any, have you experienced in regular working. Have you found it difficult to keep to timetable and can you make up for any time lost on journey.*

Alexandra (Newport) Docks and Railway. — No.

Furness Railway. — No difficulties have been experienced.

Great Western Railway. — No difficulty in meeting the requirements of the various services. Not the practice to make good in running the time lost at stations, but the times at terminals is reduced.

Lancashire & Yorkshire Railway. — The engines are of sufficient power to handle the loads they have to work satisfactorily and maintain the booked services. In some cases where the speeds are comparatively low, time can be regained between stations.

London & North Western Railway. — The engine is sufficiently powerful for its purpose and in every other respect is satisfactory. Time can be made up if required.

Midland Railway. — With regard to the regularity of travelling and time table working, no difficulty has been experienced.

North Staffordshire Railway. — Our rail motors work very well especially when not hauling a trailer coach but on some parts of our line we do not find it an easy matter to keep time when a trailer is attached, and consequently it is not often that we can make up for loss of time.

North Eastern Railway. — Power sufficient for the service. Smoothness very good. No difficulty in keeping to the scheduled time under ordinary conditions, but under adverse conditions power insufficient to allow of loss being made up.

Rhymney Railway. — No loss of time.

Taff Vale Railway. — The working is satisfactory. A vehicle runs smoother when separate from the motor. No difficulty. Time can be made up.

Dublin & South Eastern Railway. — No difficulties have arisen in working. Time can be made up.

Central South African Railways. — When working normally the locomotive power on these cars has proved sufficient to run the services to time under all conditions of weather, etc.

South Australian Government Railways. — On the whole the results are considered satisfactory.

Great Indian Peninsula Railway. — No difficulty. Time can be made up but to only a very small margin.

Madras & Southern Mahratta Railway. — Runs generally to time. If time is lost there is possibility of making it up.

North Western State Railway of India. — No. Booked at 26 miles per hour. Time can be made up.

Question 5. — *a) Have you found any difficulties in the upkeep of the boiler, or the automotor having regard to the more delicate construction than that of an ordinary locomotive. — b) Has the boiler given trouble on account of the quality of the water used. — c) Do you keep spare motor trucks or engines to replace engines failing or requiring repairs.*

Alexandra (Newport) Docks and Railway. — *a*) No. — *b*) No. — *c*) No.

Furness Railway. — *a*) No. — *b*) No. — *c*) No.

Great Western Railway. — *a*) No especial difficulties after experimental stage. — *b*) Trouble only to the same degree as with locomotive boilers. — *c*) Yes.

Lancashire & Yorkshire Railway. — *a*) Difficulties have been experienced with the two-barrel type only. — *b*) No more trouble than previously with the ordinary engines. — *c*) No.

London & North Western Railway. — *a*) No. — *b*) We have had to soften the water at two stations for the use of two of the cars. — *c*) These trucks containing the engine and boiler and mechanism complete can readily and easily be changed, and thereby the car itself can be kept in continuous service and not required to stand idle while the engine is under repairs. One spare engine complete is provided for the purpose.

London, Brighton & South Coast Railway. — *a*) The engines have given no more trouble either as to boiler or engine details. In fact the repair account for them is lighter. — *b*) Not more than with the large types. — *c*) No.

Midland Railway. — *a*) A vertical fire tube boiler was originally fixed, but this was not satisfactory for steam raising. This has been replaced by a locomotive boiler and the results are now quite good. — *b*) No special trouble has been experienced with regard to the water used. — *c*) No spare trucks are kept.

North Staffordshire Railway. — *a*) No very serious difficulties. — *b*) The water we generally use for the rail motors is fairly good, but when giving the vehicle general repairs we have had to take several of the bottom rows of tubes out to clear the scale out of the boiler barrel and around the tubes. — *c*) No.

North Eastern Railway. — *a*) No. — *b*) No. — *c*) Yes.

Port Talbot Railway. — *a*) No. — *b*) No. — *c*) No.

Rhymney Railway. — *a*) No. — *b*) No. — *c*) No.

South Eastern & Chatham Railway. — *c*) We do not keep spare motor trucks.

Taff Vale Railway. — *a*) No. — *b*) Yes our water incrustates badly. — *c*) We have two spare motor engines.

Dublin & South Eastern Railway. — *a*) No. — *b*) No. — *c*) No.

Great Northern Railway (Ireland). — No spare parts.

Central South African Railways. — *a*) No particular difficulties have been experienced in service with the boilers or engines of our cars. — *b*) No boiler trouble attributable to the water used. — *c*) Spare motors not provided. When it becomes necessary to take a car out of service for shop repairs, a small locomotive and a coach of suitable design is put on the work.

South Australian Government Railways. — *a*) No. — *c*) Spare wheels and axles are kept in stock.

Great Indian Peninsula Railway. — *c*) No.

Madras & Southern Mahratta Railway. — *b*) Yes. — *c*) No.

North Western State Railway of India. — *a*) No. — *b*) No. — *c*) No.

QUESTION 6. — *a) Do you find that cars if stabled in locomotive sheds suffer deterioration in the upholstering and accessories through any difficulty in keeping them in a good state of cleanliness and. — b) Have they proved in any way an incumbrance at the depots.*

Alexandra (Newport) Docks and Railway. — *a*) We have a separate shed for cars. — *b*) No.

Furness Railway. — *a*) Cars are not stored in locomotive shed with a view to avoiding these troubles. — *b*) Yes.

Great Central Railway. — *a*) No.

*

Great Western Railway. — *a*) No deterioration of body of car, upholstering, etc., that could be attributed to the cars stabling in the same shed as locomotives or to the fact that the mechanical portion is attached to the car. — *b*) No complaint as to cleanliness. No delays or special difficulties owing to locomotive depots being used by cars.

Lancashire & Yorkshire Railway. — *a*) No. — *b*) The additional room required has on occasions caused inconvenience at sheds.

London & North Western Railway. — *a*) No trouble whatever. — *b*) No.

London, Brighton & South Coast Railway. — *a*) The trouble in class 1 is met by detaching the car, the engine going to shed in ordinary way after putting the coach away in siding, or dock in stations. — In class 2, the seats are covered in split cane and the cars being run on branches where the engines making shed are not many, no trouble has so far arisen.

Midland Railway. — *a*) The difficulties of maintenance in repairs and cleanliness of these cars are somewhat enhanced by the fact that there is generally no shed accommodation for them, but as we have no great number of this class of motor, they have not proved to be a special encumbrance to the depots.

North Staffordshire Railway. — *a*) Having a separate shed for the motor cars we are not much troubled in this way. — *b*) Our cars are not very long ones so that not much trouble is experienced.

North Eastern Railway. — *a*) No. — *b*) No.

Port Talbot Railway. — *a*) We have experienced no trouble this way, as we stable the motor and car in the carriage shed, a smoke ventilator being fixed in the roof.

Rhymney Railway. — *a*) No. — *b*) No.

Taff Vale Railway. — *a*) The chief deterioration is the swelling of the mahogany panels due to moist steam which affects the glue and results in drawing the panel pins securing the panels. — *b*) Yes they take up a lot of room.

Dublin & South Eastern Railway. — *b*) No.

Great Northern Railway (Ireland). — *a*) No. — *b*) No, as special sheds are provided.

Central South African Railways. — *a*) The design and arrangement of our cars is such, that though stored in the locomotive running sheds, rapid deterioration of the upholstery and accessories does not take place. — *b*) The extreme length of the cars has given no trouble at the locomotive depots, but as regards light repairs to the coach itself in the steam sheds, it has been found inconvenient and costly, as men have to be brought from a workshop, strict supervision being impossible.

South Australian Government Railways. — *a*) No. — *b*) No.

Madras & Southern Mahratta Railway. — *a*) No. — *b*) No.

North Western State Railway of India. — *a*) No. — *b*) No.

QUESTION 7. — *Have you often found it necessary to replace the automotor cars by ordinary engines and trains when traffic is heavy on holidays, etc., and in cases of breakdown of the cars.*

Alexandra (Newport) Docks and Railway. — No; but we have run supplementary trains worked by locomotive when specially needed.

Furness Railway. — Yes.

Great Central Railway. — Yes.

Great Western Railway. — Rarely.

Lancashire & Yorkshire Railway. — In two cases, the service on Saturday afternoons is worked by locomotives and ordinary carriages owing to the heavy traffic, but on the other branches, this is an unusual occurrence. Mishaps occasionally occur and on such occasions another car is brought into use when one is available, but if another car is not at liberty, an ordinary steam train is run.

London & North Western Railway. — No.

London, Brighton & South Coast Railway. — An extra coach is attached on such occasions alternately to the engine or motor coach according to the direction run.

Midland Railway. — This question has been partly auswered, see II-12. In case of accident, an ordinary train is substituted for the car.

North Staffordshire Railway. — At holiday times chiefly, we have to set aside the cars from their ordinary working but we sometimes use them on these occasions to run between trains to carry passengers from place to place.

North Eastern Railway. — Not at all. Second car brought into use when necessary.

Rhymney Railway. — On bank holidays, fete days etc., when there is a great rush of passengers, the motor cars are put aside, replacing them by trains hauled by locomotives.

Taff Vale Railway. — Occasionally but not often.

Dublin & South Eastern Railway. — Yes.

Central South African Railways. — The number of passengers offering on the routes served by our cars is more or less constant. It has not been found necessary to make extraordinary arrangements for passenger rushes.

South Australian Government Railways. — It has at times been found necessary to replace these motors with trains, but not often.

Madras & Southern Mahratta Railway. — Motor cars are run independent of other ordinary trains to booked timings and are not cancelled in cases of heavy rush of passengers.

North Western State Railway of India. — Yes.

QUESTION 8. — *Have you found any advantage in reducing classes to one only even for trailing cars.*

Alexandra (Newport) Docks & Railway. — Always had one class.

Furness Railway. — No.

Great Central Railway. — No.

Great Western Railway. — One class only used. Advantage in seating.

London & North Western Railway. — No : no trailing cars used.

London, Brighton & South Coast Railway. — All the motor cars, trailer and otherwise, are one class only, and no disadvantage of any kind has become apparent.

North Staffordshire Railway. — It simplifies matters to some extent, and we find that 3rd class accommodation is that mostly required. When we run a trailer coach, it is one with 1st and 2nd class accommodation usually.

Rhymney Railway. — Third class only is carried in the motor cars, also in the trailing cars. This is found advantageous as the 3rd class passengers are numerous in the district where the cars run.

Taff Vale Railway. — We find it best to have two *viz.* : 1st and 3rd.

Dublin & South Eastern Railway. — Have not reduced the classes to one.

Central South African Railways. — One of these cars has one class only; the other, two classes. Routes are allocated to these cars to suit the class of accomodation required.

South Australian Government Railways. — It has not been tried.

Great Indian Peninsula Railway. — Two classes instead of three are available. No advantage beyond that it would have been impossible to have accommodated 3 classes economically in the limited space.

Madras & Southern Mahratta Railway. — No.

QUESTION 9. — *Has the number of automotor car journeys sandwiched between existing passenger trains caused obstructions or delays, particularly on sections of the line over which express trains are run.*

Alexandra (Newport) Docks & Railway. — No.

Great Central Railway. — To some extent.

Great Western Railway. — No.

Lancashire & Yorkshire Railway. — No. The services are timed so as not to obstruct other trains.

London & North Western Railway. — No.

London, Brighton & South Coast Railway. — No.

Midland Railway. — No.

North Staffordshire Railway. — No.

North Eastern Railway. — No.

Rhymney Railway. — No.

Taff Vale Railway. — On crowded sections of the line-yes.

Dublin & South Eastern Railway. — No.

Central South African Railways. — The motor train services are arranged with reference to the ordinary traffic in such a manner as to obviate the possibility of any disruption of the general traffic working.

South Australian Government Railways. — No.

Great Indian Peninsula Railway. — Not so long as they run to time.

Madras & Southern Mahratta Railway. — No, our motor service is limited.

QUESTION 10. — *Average consumption of fuel per mile including consumption for lighting and stoppages.*

Alexandra (Newport) Docks and Railways. — 12·37 lb. per mile.

Furness Railway. — 28 lb. per mile.

Great Western Railway. — 18 lb.

Lancashire & Yorkshire Railway. — 27·23 lb.

London & North Western Railway. — 24·38 lb. per train-mile.

London, Brighton & South Coast Railway. — Class 1 : 16·4 lb. — Class 2 : 14·5 lb. — Class 3 : 1.82 pints of spirit.

Midland Railway. — Class 2 : 30·05 lb. of coal. — Class 3 : 37 lb. of coal.

North Staffordshire Railway. — 26 lb.

North Eastern Railway. — 3 1/2 miles per gallon of petrol or 28 gallons per mile.

Port Talbot Railway. — 16·3 lb.

Rhymney Railway. — Average consumption of coal per mile 20 ?5 lb. taken over 6 months.

Taff Vale Railway. — Average 23 3/4 pounds. Large cars, 26 lb. Small cars, 22 1/2 lb.

Dublin & South Eastern Railway. — 24 lb. of South Wales coal per mile.

Central South African Railways. — 28 3 lb. per mile.

South Australian Government Railways. — 14 lb. per mile.

Great Indian Peninsula Railway. — 41·76 lb. per mile.

Madras & Southern Mahratta Railway. — 33 lb.

North Western State Railway of India. — 21 lb. per mile.

RAILWAY.	QUESTION 11. — *Average cost per mile for greasing, lighting, water, traction staff, cleaning, upkeep of mechanical part and of car.*								
	Oiling.	Greasing.	Lighting.	Water.	Traction staff.	Cleaning.	Mechanical part.	Car.	Total.

QUESTION 12. — *Data similar to those asked for by the questions Nos.* 10 *and* 11 *for the small locomotives dealt with at questions* 1-13 *or for the ordinary tender locomotive dealt with at question* 1-14.

Taff Vale Railway. — Coal 38 pounds per train mile. 8·025 pence per train mile including renewal charges but exclusive of cost for carriages.

South Australian Government Railways. — Class Z average consumption per mile 32 lb. Average cost per mile 13·17 pence.

QUESTION 13. — *Average price of the automotor cars for your various types in comparison with the price of the locomotive dealt with in the foregoing questions.*

Furness Railway. — £2,328.

Great Western Railway. — Motor car £2,000. Small engine (estimated) £1,600. We have not constructed any of the small engines for many years.

London & North Western Railway. — Average cost £2,000.

Midland Railway. — Class 1 : C. & W. work £736. Locomotive work (only) £1,000. — Class 2 : tank engine (estimated when new) £1,600. Now adopted for automotor work. — Class 3 : tank engine £2,365. Now adopted for automotor work.

North Staffordshire Railway. — The price of our rail motors averaged about £2,000 each.

North Eastern Railway. — Cost of automotor cars about £3,000 each.

Rhymney Railway. — Cost of steam motor car £3,250.

Taff Vale Railway. — Large cars £2,380 each. Small cars £2,069 each.

Dublin & South Eastern Railway. — £2,780.

Central South African Railways. — Class 1 : this car consists of a side door suburban coach whose original cost was £2,401 converted to suit this class of traffic, such conversion costing £1,710 for both engine and coach. The engine was reclaimed from scrap. Its cost new was £1,715. — Class 2 : £4,653·12*s.* 8*d.*

South Australian Government Railways. — Motor car £2,311. Passenger engine £2,976.

Madras & Southern Mahratta Railway. — 29,071 rupees.

North Western State Railway of India. — 35,000 rupees approximately.

QUESTION 14. — *Have you other automotor cars building? Of what type? Do you intend extending the use of them?*

Furness Railway. — No, Not at present.

Great Central Railway. — No.

Great Western Railway. — None building at present.

Lancashire & Yorkshire Railway. — No.

London & North Western Railway. — We have none building at present. No.

London, Brigton & South Coast Railway. — Other engines of the small type will be converted for trailer service as they pass through the shops.

Midland Railway. — No other cars building.

North Staffordshire Railway. — No.

North Eastern Railway. — No.

Port Talbot Railway. — No. We do not intend extending the use of them.

Rhymney Railway. — The Company have no motor cars now building and do not require more cars at present and therefore have not considered the question.

Taff Vale Railway. — No.

Dublin & South Eastern Railway. — No.

Great Northern Railway (Ireland). — No.

Central South African Railways. — We are not at present building more cars of either type but we are considering the design for a car for branch lines, the type to follow closely No 1 motor *viz.* : a small locomotive attached to a specially designed coach. This type of car has many advantages over those of the No. 2 motor type and the design of all future cars added to our stock will probably in the main follow that of this car. The self contained type of car such as motor No. 2 is not satisfactory, especially as regards confort for passengers, ease of detachment, and complication and number of spare parts. The latter point is important, in so far that very few of the parts of the self-contained car can be made interchangeable with those on ordinary rolling stock.

South Australian Government Railways. — No.

Great Indian Peninsula Railway. — No. When the service is extended, it will be by the adoption of small locomotives passed service for regular traffic.

Madras & Southern Mahratta Railway. — No.

North Western State Railway of India. — No.

APPENDIX II.

Reply of the North Eastern Railway (England).

QUESTIONS 1 to 11. — *Rail auto-motor cars.*

The driving power provided consists of a four cylinder horizontal petrol engine, built by the Wolseley Tool and Motor Car Company, of Adderley Park, Birmingham, and rated at 80 B. H. P. at 420 R. P. M.

This drives a compound wound and separately excited dynamo rated at 55 kilowatts, which supplies current to two 60 H. P. B. T. H. tramway and motors mounted on the front bogie of the car.

With the exception of these motors, the whole of the electrical equipment was supplied by the British Westinghouse Electrical & Manufacturing Company, Trafford Park, Manchester.

The petrol motor has cylinders 8 1/2 inches diameter, by 10 inches stroke, and is designed for a normal speed of 420 R. P. M. but can be accelerated to 480 R. P. M,, and this is done in getting the car under way. The crankshaft, of the "two throw" pattern is constructed of Vickers-Maxim cast steel. The cranks are, of course, completely enclosed, the inspection covers of the casing being at the top, and an oil trough below. Two cylinders placed vis-a-vis drive on to each crank. There are two cam-shafts, one on each side of the engine, and the whole of the valves are mechanically operated.

The cylinders and valve boxes are water jacketed, the temperature of the circulating water being kept down by a Clarkson Radiator cooled by the blast from a Blackman fan.

The armature of the generator is mounted on an extension of the crankshaft and there is a 3 feet flywheel between the armature and the engine casing. This generator is compound wound, and separately excited, and is specially designed for operating over a range of 300 to 500 volts. The field is split horizontally, so that the upper portion may be removed through an opening in the roof of the car when access to the armature is desired. The exciter is driven by belting from a pulley on the outer end of the generator shaft. This exciter is shunt wound, and is used also for running the 30, 16 C. P. power, 72 volt electric lamps with which the car is lighted, and can further be used to furnish current at 95 volts, for changing a secondary battery of 38 cells, each rated at 120 ampere hours, which is fixed beneath the floor of the car. The whole of the generating plant is fixed in the front compartment of the car, which is 13 ft. 3 in. long.

The controllers are of the standard pattern (tramway type) and one is fitted at each end of the car.

In starting up, the engine is driven, for a turn or two, by the generator acting as a motor and taking current from the secondary battery. Once the engine is up to speed, and the voltage has been adjusted to 400 volts, the car is started by the controller in the usual way. For slow speeds the car is run with the motors in series and for high speeds with them in parallel. The

voltage of the generator is gradually increased to 500 volts, by cutting resistances out of the exciter circuit and the car will then accelerate until a speed of 35 miles per hour is attained. In stopping the car, the controller handle is moved back to the off position and then over in the reverse direction to apply the Westinghouse track brakes, with which the car is provided. These consist of two electro-magnets suspended between the wheels. When the magnets are excited, the shoe with which they are provided is attracted on to the rail, thus acting as a track brake.

At the same time, the downward motion of the magnets also applies brake shoes to the wheels, and a further retarding action is attained through the fact that the current for these magnets is obtained from the motors acting as dynamos, so that the brake does not depend for its current on the generator plant.

The cars are very comfortably fitted up. There is a gangway between the two rows of reversible seats, and the floor is covered with linoleum.

Each car is fitted with buffers and coupling hooks of the standard railway carriage pattern, so that it can be run with the ordinary rolling stock if necessary.

The time taken to get ready for work is only 10 minutes and a full days supply of petrol is carried.

QUESTIONS **1** to **13.** — *Steam autocars.*

The railway companies are now finding the advantage of having a number of self-propelled coaches to supplement the ordinary train service in times of heavy traffic, or to work on branch lines between stations where the traffic is not sufficient to warrant the cost incurred by running ordinary passenger trains.

Several companies have built special vehicles with a small steam engine driving on one bogie, but the North Eastern Railway Company, having a number of small passenger tank engines which are not powerful enough to cope with normal present day trains, determined to utilise these for similar purposes, and thus save the expense of building a combined vehicle. For this purpose, the engine is coupled up to an ordinary carriage slightly altered. The exterior view is shown on the enclosed photo. The reversing screw and regulator handle are coupled up by means of sprocket wheels and chains to two small shafts under the buffer beam of the engine; they are provided with universal joints and telescopic movement on account of curves, etc., and extending under the coach underframe to the other end where they are coupled up to handles similar to those a driver is used to on a locomotive. These are placed in a compartment at the front end of the coach, which also contains the Westinghouse Brake drivers handle connected with the main air reservoir on the locomotive. When the engine is leading, the driver is in his normal position with the fireman, but when running in the opposite direction he communicates with him by means of a speaking tube. In the event of a failure on the locomotive, when the driver is not on the foot-plate, the auxiliary driving gear is so arranged that it can be thrown out of action and the locomotive stopped by the fireman. The idea has been further developed on some sections, and the engine being placed between two of these fitted coaches, in each of which is a drivers compartment.

A great many of these "steam autocars" are now running.

APPENDIX III.

Time-Tables.

SECTIONAL DISCUSSION

(2nd and 3rd SECTIONS MEETING JOINTLY)

Meeting held on 6 July, 1910 (morning).

MR. GERSTNER IN THE CHAIR.

The President. (In French.) — Gentlemen, the 2nd and 3rd section are meeting jointly today in order to discuss question XII, but as this question is also of interest to the members of the 5th section, who deal with light railways, I think it would be advisable to ask them to join us. If there is no opposition, this shall be done.

2nd, 3rd and 5th SECTIONS MEETING JOINTLY.

Mr. Gerstner. (In French.) — Gentlemen, I propose to the three joint sections to appoint Mr. Dietler, president of the 3rd section, to be our president. (*Approval.*)

— Mr. DIETLER takes the chair.

The President. (In French.) — Gentlemen and dear colleagues, I thank you for the confidence you kindly show in me and I venture to hope for your kind cooperation.

I propose to you that we should hear the reporters in the order given in the list of questions. As the first reporter, Mr. Riches, is not present, I call upon Mr. C. Peter Clark to give a summary of his report.

Mr. C. Peter Clark, *reporter for America.* — There are Gentlemen, conclusions, presented at the bottom of the report I wrote on question XII, and which has been distributed to the members of the Congress :

The fact that interest in this subject continues on every side and that different roads and Companies continue to produce new types of apparatus upon the same general line is a very encouraging sign.

The question of expense, first cost of repairs and depreciation cannot be satisfactorily determined by the performance of isolated cars under different weather and topographical conditions where the prices for the same kind of fuel and service vary greatly.

The marked tendency of the past three or

*

four years based upon the numbers built, is unquestionably in favour of the car operated by gasoline and without the additional electrical complications, but this, by no means, proves that the experiments of the next three or four years may not introduce new features giving even more satisfactory apparatus at less cost and susceptible of even cheaper operation.

The amount at stake is so large that the continued study of the subject is clearly warranted, and circumstances appear to justify the belief that apparatus of this kind alone will enable steam railroads to protect passenger business which otherwise will be lost to them.

Since the publication of the report, with the conclusions which I have just read, the situation in America has changed but little, except that the building and orders for motor cars have increased considerably, which shows that this question is receiving much attention.

The report states the fact that the passenger trains of the United States carry an average of fifty-four passengers; by deducting heavy trunk line trains and suburban trains near large cities, it is evident that a large portion of the trains in the United States are handling a traffic which could be very well taken care of by a single motor car of reasonable dimensions.

The various types of motor cars are classed as follows :

A. — *Motor cars driven by steam using coal as fuel.* — This type is but the development of similar cars built many years ago in America, which never met with general favour, on account of their cost, and because the coal and machinery are so heavy and bulky.

Motor cars driven by steam using oil as fuel. — The firing in this case is simplified, but the employees refused to accept the reduction of the number of men on locomotives made possible by the substitution of oil for coal, and it is quite probable that they will take the same position towards motor cars.

Up to this time there have been but experimental cars of this type.

B. — *Motor cars driven by internal combustion engines with a mechanical transmission of power.* — In June 1909 there were but forty-six cars of this type, built according to the Mac Keen patent; but in May 1910, seventy-five of them were in service, which shows a general disposition in favor of this type of car.

C. — *Motor cars utilizing internal combustion engines operating dynamos in connection with an electric drive with or without storage batteries.* — The report refers to two types of this kind : the first being an experimental car built by the General Electric Company, which had been in service but a short time at the writing of the report.

Since then, this car has given such good results that 13 of this type have been ordered by six different companies, and negotiations for more are being conducted.

It will be about two months before these cars are ready for service, but the orders denote the best judgment of those who have studied the construction and the service of the experimental car.

We hear nothing of new orders for the type of car quite similar, described in the report under the heading of " Strang gas-electric car ".

In examining the present condition of

the development of motor cars in America, we note the preference shown for the gasoline car; it is still an unsettled question, however, whether the benefit of the electric transmission is sufficient to offset the additional weight represented by the dynamos and motors, which necessarily increases the expense of building and maintenance.

This question cannot be definitely solved by results obtained from the service of one or two experimental cars for a few months; but will require a longer and more general service for definite results.

In conclusion, I have no modification to propose to the summary presented in the report as prepared and printed in 1909.

Mr. Greppi, *reporter for all countries except Great Britain and America.* (In French.) — Gentlemen, question XII relates to motor vehicles, more especially from the point of view of use and cost. The report, of which I will give you a summary, deals with all countries except the English-speaking ones.

Of forty-three administrations who sent answers to the list of questions, twenty-six replied that they had no motor cars or equivalent small locomotives in use; that they never had any and did not intend to have any built.

The Baden State Railway has made trials with two motor cars, no longer used. Three other administrations limit themselves to the statement that they operate several services of a local character with small tank locomotives of old types. This only leaves thirteen answers from administrations who are at present trying motor cars or using them in the regular service.

In my report I have also described the motor luggage vans which more or less resemble motor cars. The same applies to trials and investigations made with a view to utilizing small locomotives instead of motor cars. On the other hand, I have left out of consideration the electric cars taking current from outside.

The thirteen administrations which answered the list of questions own 195 motor-cars which, classified according to kind of motor, give the following groups:

185 steam motors, 85 being motor luggage vans;

7 motor cars with internal-combustion motor;

3 electric accumulator motor cars.

These figures do not include the luggage-van locomotives of the French State Railway and the small locomotives which are being tried by the Baden State Railway and the Austrian State Railway; all of these have steam engines.

It has also to be remarked that there are motor cars of recent type on trial or in use on lines belonging to some administrations which did not answer the list of questions. Such are the Stoltz steam cars, the petrol cars and the accumulator cars in Prussia, and the benzo-electric cars of the Weitzer type in Hungary. Another new type of benzo-electric car will be tried in Belgium on local lines.

It may however be said that the development of motor-car services, which seemed in full activity from 1900 to 1907, has rather stopped during later years.

As regards kind of motor, steam cars are still the most numerous, in spite of the nearly inevitable disadvantages they have. In more recent investigations, there seems to be a tendency in favour of petrol

motors, which are probably more suitable for the services for which motor cars can be used. But it seems that as yet no satisfactory type for current use has been evolved.

As regards the dimensions of the cars, the most recent designs show a tendency to prefer cars with three and with four axles, rather than cars with two axles, which have a very small capacity.

Nearly always in the four-axle cars, and often in the three-axle cars, we find a separate motor truck, with two axles supporting the whole motor; this motor truck can be removed for purposes of repair from the carriage body and afterwards replaced.

The smallest units are represented by the Ganz type, with de Dion steam motors of 30 to 35 horse-power car with two axles, weighing 13 tons empty and 16 tons when loaded, and by the Daimler petrol type, having nearly the same weight. The heaviest are the four-axle cars of the Italian State Railway and the Bavarian State Railway, with motors of about 200 horse-power, and weighing up to 43 tons empty and 52 tons when loaded.

The corresponding maximum axle-loads vary between 11 tons and about 15 to 16 tons respectively.

A tendency towards simplification, either in design or in working, is shown by the reduction in the number of classes. In some cases there is only one single class.

A rather long platform is always provided, affording standing room for a certain number of passengers.

In recent types the continuous brake is nearly generally adopted and steam heating is always used in the case of steam cars, and hot-water (the cooling water from the motors) heating in the case of cars with internal-combustion motor. Coal stoves are still to be found in the accumulator cars, of which however there are but few.

As regards draft gear and buffing gear, there are only two cases where special provision is made in the case of cars which are intended always to travel by themselves, or only to haul a special trailer: the petrol car of the Swiss Federal Railway and the benzo-electric cars, on the Weitzer system, which it appears are used on the Arad-Csanad Railway.

Coming now to the mechanical part of the subject, we find the following types of boilers used in the steam cars: ordinary boilers with smoke tubes, of the locomotive type, are used on the old Belpaire cars of the Belgian State Railway, on some of the four-axle cars of the Bavarian State Railway and on the four-axle cars of the Italian State Railway. The boiler is placed crosswise in one of the two types of the Italian State Railway, but this arrangement has been given up and is altered when repairs are being carried out, the objection being the displacement of the water-level when running round curves. In the other case the boiler is placed longitudinally and the fire-door is on one side of the fire-box.

Vertical boilers with smoke tubes are used on the motor luggage vans of the Italian State Railway and on the motor cars of the Wurtemberg State Railway. In the latter, the barrel is enlarged at the upper part, like the well-known vertical boilers of the motor cars of the Great Western Railway, and the fire-box is of Fox corrugated plate.

The Italian State Railway has also, as a

trial, fitted some of its luggage motor vans with such a barrel enlarged at its upper part; this increases the reserve of water and of steam, reduces the variations in the water-level and increases the life of the tubes. A certain number of these vans has also been equipped, as an experiment, with the Komarek boiler.

I am now in a position to be able to say that of the different types of boiler used on the luggage vans of the Italian State Railway, the Komarek boiler gives the best efficiency; but the vertical boiler with its barrel enlarged at its upper part is preferred, as this has proved superior from the point of view of maintenance.

The water-tube boilers which are used on motor cars include : the Komarek type, which is in use in Austria; the de Dion, Field, Turgan, and Serpollet types of which rare instances are found in Austria, in Belgium, in Bavaria, in Wurtemberg and in France; and the well-known Purrey system, which is an improved derivative of the Serpollet system, and is used in Italy and above all in France.

There is also the Stoltz boiler used on the Prussian State Railway, but about this I have not received any direct information.

All these types are more or less well-known. Nothing new has been invented during the last few years.

Steam superheating, which is inherent in the very types of the Serpollet and Purrey boilers, is also used to a limited extent in the Kittel and Komarek boilers. The Bavarian State Railway uses the Schmidt superheater.

The working pressure varies between 12 and 16 kilograms per square centimetre (between 170 and 228 lb. per square inch), except in the case of the Serpollet and Purrey types where the pressures are very high, and in that of the de Dion boilers of the Ganz cars, where it is 18 kilograms per square centimetre (256 lb. per square inch).

The grate areas vary between 0·33 and 1·08 square metres (between 3·55 and 11·62 square feet), and the heating surfaces between 8·5 and 60 square metres (between 91·50 and 645 square feet). The corresponding power limits are about 35 and 200 horse-power.

Coke is used as fuel for the Purrey boilers and sometimes also for the de Dion boilers; in all other cases coal is used, with the sole exception of the petroleum Serpollet car on the Paris-Lyons-Mediterranean Railway, which is however no longer in use.

There is no application of the heavy-oil firing system, which is however applied on some of the small locomotives of the Austrian State Railway and which it seems can be recommended, as only one man is required on the locomotive. But difficulties would be encountered in adapting this system suitably and practically to small fire-boxes.

As regards the engine, single expansion generally is used except in the case of cars of the Ganz and Purrey types.

I have nothing fresh to say about the few accumulator cars, none of which are new except those of the Prussian State Railway, about which I have received no information.

The sole type of petrol motor used on the motor cars on this Continent is the Daimler. As yet there is in Europe no application of the gasoline motors of recent type which are in use in America.

It occurs to me, however, that certain designers are considering the use of motors in which heavy oils are burnt, such heavier oils being cheaper than petrol or gasoline.

An important problem which arises in the case of motor cars, and which is connected with the system of working adopted, is that of the controlling gear, with a view to running in both directions.

The ideal solution of perfect symmetry is only attained in the petrol cars and in the accumulator cars.

In the case of a certain number of steam cars, the problem of running in both directions has been left out of the question; as hort wheelbase has been adopted so as to make it possible to turn the cars on the ordinary turn-tables at the stations, as in the case of the motor luggage vans of the Italian State Railway, or on the locomotive turn-tables, as in the case of the Ganz and the Purrey cars.

It is, however, interesting to note the method adopted in the case of the three-axle Purrey cars, with motor truck, on the Orleans Railway; these are turned by means of an auxiliary traverser which receives the third axle of the car and runs on a circular track concentric with the turn-table which has a diameter of 4·400 metres (14 ft. 5 $^1/_4$ in.).

The solution frequently adopted in England, which consists in utilizing a little train formed with two bogie carriages and a locomotive or motor car in the middle, having a rather larger loading gauge, has received no applications on the Continent.

In all the other cases, the cars have a fully-equipped cab at the end where the engine is, and at the other end, an auxiliary cab or a simple post of control occupied, when running backwards, by an employee. The appliances the latter generally has available are the valve operating the brakes, a compressed-air or steam whistle and a lever for closing the régulator.

An exception is formed by the small Serpollet and Kittel cars on the Wurtemberg State Railway, on which there is only a whistle and an extra brake valve at the post of control; the employee there must not intervene except in the case of danger. The cars of the Kittel type have cabs with a larger cross-section so as to enable the driver to see the track when running backwards.

The problem of replacing motor cars by small locomotives of special design has been closely investigated by the Bavarian State Railway and the Austrian State Railway. The latter has in use two small locomotives, with two axles, with fire-boxes heated by petroleum residues, the burners being of the Holden type. The Bavarian State Railway uses for its local services sixty small locomotives designed by the firms Maffei and Krauss. I should very much like to obtain information, from the Bavarian delegates, about the working results of these locomotives.

The French State Railway still uses its luggage-van locomotives of an already old type, capable of hauling up to sixteen axles.

Passing now to the question of the organization of motor-car services, I find that the use of motor cars alone is rather rare, evidently because such a train unit is too small to meet the least variation in the number of the passengers.

The number of trailers is usually two or

three, and attains four and five in the case of motor cars with powerful boilers.

The typical light train of the Italian State Railway consists of a motor luggage van hauling two four-axle carriages of large capacity designed for the local services, or else of a motor-car hauling a trailer which also has four axles.

Intercommunication between the motor car and the trailers by means of gangways for the employees is not generally provided.

No administrations allow automotor cars or small locomotives to push other cars; this practice is adopted by some of the English companies.

The use of one single man as driver and of one conductor or guard is a rule without exception in the case of petrol cars and of accumulator cars. The same system is generally adopted on the lines which use steam cars of the Serpollet, Purrey and Kittel types, with or without trailers.

In the other cases, this system is not generally applied.

The cars of the Ganz and the Komarek types and the Bavarian State Railway four-axle cars are worked by two or by three employees, according to the condition of the service and the compositon of the train.

In Belgium and in Italy, the steam cars with boilers of the locomotive type or vertical boilers are generally looked after by two engine men, plus a conductor.

In principle, the possibility of having a single traction employee, which is one of the most important factors in reducing the working expenses by the use of automotor cars, depends on several conditions which it is not always possible to realize fully when using steam engines.

As regards design, in the first place it is necessary that the driver should have a good view of the track and the signals, and everything possible must be done to reduce the attention the boiler requires to a minimum, either by the use of a semi-automatic stoking appliance, or by that of liquid fuel.

Experiments of this kind have been made on the Bavarian and Austrian motor cars. It would be desirable that the delegates of those countries should inform us of the results obtained.

Besides the solutions already mentioned, the reduction of the traction staff to one driver can also be realized when the load is limited, the gradient is easy, the stops not far apart and the whole run a short one, for it is then possible to do the firing work during the stops, and the variations in the water-level while running are reduced. Another condition also required is that the line should not have too many trains running on it, or have too many signals, junctions, etc.

Finally, assuming that the traction staff can be reduced to one man, it is necessary that one of the guards or the conductor should be able to take his place in case of necessity. In order that the whole number of men on the train may be reduced to two or three, according as one or two are required for the engine, there must be intercommunication between the motor car and the train, or else the continuous brake must be available and the number of trailers must not exceed two or three.

It must also be remarked that difficulties opposing a reduction in the staff are sometimes caused by the employees themselves.

When motor cars are available having

the motor at one end and at the other an auxiliary post of control, it is more usually the driver who takes his place on the latter while running backwards. On some lines, however, the driver remains by the motor and the fireman takes the other post.

The mileage of motor cars per day of service is, according to the information received often less than that of the locomotives. This is explained by the short length of the runs or by the very character of the auxiliary service, intercalated between the chief trains, for which the motor cars are used.

The mean annual distance covered varies, according to the figures received, between 8,000 and 33,000 kilometres (between 4,970 and 20,500 miles). The coefficient of utilization, that is the ratio between the number of days of service per year and the number of days in a year, or else the ratio between the actual mileage of each unit and the theoretical mileage represented by 365 times the daily mileage, appears to be appreciably less in the case of motor cars than in that of locomotives.

According to the answers I have received, this coefficient varies between 29 and 65 per cent, whereas it varies with locomotives, in my opinion, between 70 and 75 per cent.

The use of small train units gives rise to certain problems in connection with the operation of the traffic, problems which generally do not arise when locomotives are used.

Certain administrations consider the motor-car trains to be trains with a limited number of places, and the public is informed of this. But more frequently locomotives are substituted for the motor cars, or extra trains are arranged if there is an exceptional rush of passengers. The former of these two methods seems to be preferred, as regards the requirements of the public.

Difficulties of this kind have arisen more especially when motor cars of low power were used.

Motor cars are more frequently used in order to form local trains intercalated between those hauled by locomotives. There are, however, in France, in Italy, in Belgium and in Bavaria, several instances of such motor cars being used for the whole of the passenger service on secondary lines.

In that case, goods trains are run. But this system of operation is not convenient if there is much cattle and quick-freight traffic, requiring a number of trucks beyond the power of the motor car, but not justifying the expense of trains hauled by locomotives expressly run for the purpose at certain hours.

From the point of view of facilities in the use of motor cars, the distance which can be run without taking in supplies is important.

From this point of view, cars with an internal-combustion motor, also to be recommended from the point of view of the better utilization of the room available and from that of cleanliness, are the most suitable.

The distance the Daimler petrol cars can run without taking in stores is about 280 kilometres (174 miles).

As regards the regularity and the flexibility of the service, the administrations which have tried or which use motor cars of small size and of low power are those who make most complaints. Such complaints

are made by the Saxon State Railway, the Swiss Federal Railway, the Paris-Lyons-Mediterranean Railway, about the Serpollet cars; by the Italian State Railway about the Purrey cars; and by the Wurtemberg State railways about the Daimler and the Serpollet cars.

The want of flexibility is also admitted by railways which, like the Bavarian State Railway and the French State Railway, use cars of medium power.

It is remarked that although the flexibility required in the service is definitely limited by the limited dimensions of the boilers, it is always possible to ensure sufficiently regular running by having time-tables allowing a sufficient margin; this comes to the same thing as reducing the inclusive speed.

The administration of the Wurtemberg State Railway reports that its most recent cars with Kittel boilers give every satisfaction when used for its local services, and that the irregularities in running are neither greater nor more frequent than with the locomotives. The Paris-Lyons-Mediterranean Railway expresses the same opinion about its Purrey cars.

As regards difficulty of maintenance, most of the administrations which have used motors or boilers of special types state that maintenance is more costly than in the case of locomotives, owing to the special character and the complication of the mechanism.

However, the Purrey cars, which gave some trouble on the French State Railway, work well on the Paris-Lyons-Mediterranean Railway, subject to careful washing out.

The administration of the Wurtemberg State Railway declares that the upkeep of boilers of the Kittel type is not more costly than that of locomotive boilers.

The Italian State Railway has had trouble with vertical boilers, in consequence of leaks at the tubes and of the costly maintenance due to excessive utilization at the start. The boilers when modified and used for less heavy work give satisfaction.

The upkeep of horizontal boilers of the locomotive type, as compared with that of locomotive boilers, has given rise to no special remarks.

The use of spare trucks for motor cars having a motor truck separate from the main frame is considered advisable in order to reduce the immobilization of the car.

It would be interesting to have figures about the immobilization of motor cars due to their replacement by locomotives, owing to unusually busy passenger traffic; but the information obtained about this point is defective.

The substitution of locomotives on Sundays and holidays is the regular practice on some German lines; in Switzerland it is on market days.

Such substitution on fair days and market days is rather common on the Paris-Lyons-Mediterranean Railway. On the Orleans Railway, it is estimated that this substitution takes place in the case of from 5 to 20 per cent of the trains. On the Italian State Railway, this inconvenience formerly turned up rather frequently, but it has been reduced considerably by organizing the services, so that the motor luggage vans and the motor cars are only used in the cases they suit best.

One measure which is extensively and usefully adopted in order to facilitate motor-car services, is the reduction of the

number of classes to two and even to one. The administration of the Wurtemberg State Railway has adopted the single class for its services generally and finds this very satisfactory from the point of view of the simplification of the service.

The data received about the consumption of fuel vary according to the different conditions of the service. In the case of motor cars on which coal is used, the consumption varies between about 3 and 9 kilograms per kilometre (between 10·6 and 32 lb. per mile).

The information received about the cost is very limited, as was to be expected, and the data can only be compared with difficulty.

I find costs of operation varying between 16 and 62 centimes per kilometre (between 2·472*d*. and 9·579*d*. per mile).

The Austrian State Railway gives the following figures for its system :

Daimler cars	0·316	franc per kilometre	(4·882*d*. per mile).
Serpollet cars	0·309	— —	(4·774*d*. —).
Komarek cars	0·331	— —	(5·114*d*. —).
Locomotives series 86 and 185. .	0·362	— —	(5·593*d*. —).

On the Austrian State Railway, the Komarek cars cost 38,000 francs (£1,520) and 54,000 francs (£2,160), according to series, while the small locomotives of the two series cost 23,000 and 29,500 francs (£920 and £1,180).

We see that the difference between the two prices represents the cost price of an ordinary carriage with a capacity similar to that of the autocar.

On the other hand, as we have already seen, the annual mileage of the locomotives can more easily attain high figures.

My report results in the following conclusions:

1° Automotor cars can be used in certain cases for economic services, in order to facilitate local communication at a moderate outlay, provided that the traffic conditions lend themselves to the organization of frequent trains, carrying a regular traffic or at least one which only varies rarely and but little, that the line is an easy one and that the goods traffic can be carried conveniently and completely on separate trains;

2° The power of the motors of the automotor cars should present a certain margin beyond the ordinary work, so that it is possible to cope with variations of the traffic within certain ascertained limits;

3° It would be desirable to make it possible to utilize the car independently of the motor by having either separate motor trucks, or some other device making it possible to remove and replace the mechanical part easily;

4° From the point of view of economy of staff, that is to say, having only one traction agent, accumulator or petrol cars seem the most suitable. The types used by the administrations which have given me information represent units of too low a power. It would be desirable that investigations should be made in order to increase this power suitably and to ensure easy and inexpensive maintenance;

5° As regards steam cars, it would be desirable to reduce to a minimum the care required for the boiler and in particular to improve the semi-automatic feeding of the grate or to improve the methods of using liquid fuel;

6° It would be desirable to recommend the investigation of small locomotives able to replace automotor cars, with the advantage of greater independence. The luggage-van locomotives, or the motor luggage-vans, represent an intermediate solution, which it seems can be suitably applied in certain cases.

The President. (In German.) — Gentlemen, I think I am acting as your mouthpiece in thanking the reporters whom we have just heard, for their very clear and complete summaries.

If nobody objects, I think that we might take as basis, for our discussion, the conclusions given in Mr. Greppi's report, which he has just read out. The other reporter, Mr. Clark, agrees with me as to this procedure.

Mr. Greppi. (In French.) — I would request the President to ask the representatives of railways who have a considerable number of motor cars in use and who have not sent answers to the list of questions, whether they have not got any useful information which they might supply to us. I am thinking more especially of the Hungarian railways, about which I could not say anything in my report as I received no answer from them; and they use a considerable number of cars of the Ganz and the Weitzer types. I am also thinking of the Prussian State Railway, which I have incidentally mentioned in my report, and finally, of the Bavarian State Railway, which has at present in use a considerable number of small locomotives, the designs for which were worked out when that railway already had a motor-car service.

Mr. Steinbiss, Prussian-Hessian State Railway. (In German.) — The Prussian-Hessian State Railway was unable to supply any information for Mr. Greppi's report because the list of questions was either not sent to them or else went astray.

Up till 1907 only 5 steam cars had been constructed, namely 1 Thomas car and 4 Ganz cars, then later on came 2 Stoltz cars, as an experiment. Steam cars have been given up since.

In 1907 we put in use 5 accumulator cars, with three axles, 12·2 metres (40 feet) in length; their tare was 33·5 tons (33 English tons) and they took 60 passengers. The good results obtained led to the construction of 57 double cars with accumulators, 22·11 metres (72 ft. 6 1/2 in.) in length, with series motors and four axles, taking 100 passengers normally and 130 as a maximum; they weighed 54·5 tons (53·6 English tons) when empty and 63 tons (62 English tons) when fully loaded. The two cars are coupled by means of short couplings, the batteries and the cabs are at each end; they have two motors of 80 to 90 horse-power each. The maximum speed is 60 kilometres (37·3 miles) per hour and the length of run is 100 kilometres (62 miles) at a speed of 50 kilometres (31 miles) per hour on the flat and on easy gradients.

These cars, put in use in 1908, are also used on lines with short up-gradients of 12·5 per mil, and exceptionnally of 16 2/3 per mil.

At the same time a double car with 4 shunt motors of 50 horse-power was built, able to run 100 kilometres (62 miles) and to carry 95 passengers.

In consequence of the good results obtained, it was decided in 1909 to build 33 more accumulator cars with series motors and 5 cars with shunt motors (all twin, but with six axles), to be ready in 1910. One of these cars with series motors is at present at the Brussels exhibition. It is intended to build 35 new motor cars of this kind in 1911.

Besides these accumulator cars, a benzol car with electric drive was also built and

put in service in 1909, as an experiment. This car is on two Krauss bogies, and has a length of 16·96 metres (55 ft. 7·3/4 in.); it takes 81 passengers and weighs 37·5 tons (36·9 English tons) when empty and 43·1 tons (42·4 English tons) when loaded. The benzol motor develops 90 horse-power when running at 700 revolutions per minute. The dynamo is designed for a continuous output of 38 kilowatts or for one of 80 kilowatts for one hour, and the two driving motors give 50 horse-power for one hour each. The exciter absorbs 4 kilowatts.

Eight other benzol motor cars, of a modified type, are being built in 1910 and it is proposed to built ten others in 1911.

In 1909 no definite data were yet available as to working results. In 1910 it was possible to see that the results obtained with the accumulator cars in 1909 were very satisfactory. The annual mileages of the double car appreciably exceeded 50,000 kilometres (31,000 miles) and in some cases attained 70,000 kilometres (43,500 miles). Allowing for spares, the different railway managements obtained an annual average of 25,000 to 50,000 kilometres (of 15,500 to 31,000 miles) per double car.

From the technical point of view the new cars have perfectly satisfied the required conditions and are much in favour with the public on account of the smoothness of their running and the elimination of the discomforts caused by smoke. From the economic point of view they have given appreciable advantages by opening up and stimulating the traffic on branch lines, by the quicker succession of passenger trains on the main lines and by making connections with the fast trains.

The working expenses, including interest and amortization of the cars and the power stations, vary, with the cost of the current, the nature of the line and the speed of the trains, between 45 and 65 pfennige per car-kilometre (between 7*d.* and 10*d.* per car-mile); it is, however, hoped, by means of suitable improvements, to reduce this figure to a mean of 50 pfennige per car-kilometre (7·72*d.* per car-mile).

Each car has two employees on it, namely a driver and a conductor.

For some time now, in order to meet sudden rushes of traffic, trailers have been added to the accumulator cars; these are carriages with two and three axles, holding 50 passengers, and weighing 11·5 and 14·5 tons (11·3 and 14·3 English tons) when empty and 15 and 18 tons (14·8 and 17·7 English tons) when loaded, so that the motor-car trains attain a weight of 81 tons (79·7 English tons) and can carry 150 to 180 passengers. These trains run up gradients of 7 per mil at speeds of 25 to 28 kilometres (15·5 to 17·4 miles) per hour and moreover run on the flat at the normal speed of 50 kilometres (31 miles) per hour. The distance the car can run is reduced, in this case, to about 70 kilometres (43·5 miles). A third employee, acting as guard, is on the trailer.

The President. (In German.) — I would remind you that Mr. Greppi has asked whether the delegates of the Hungarian State Railway and the Bavarian State Railway had no supplementary information for us.

Mr. Greppi. (In French.) — I named the administration of the Bavarian State Railway, which has however already answered the list of questions, because I wished to

know whether it could not give us supplementary information about its small locomotives. This administration in fact told us that the small locomotives had only been in use for a short time and that at that time there were forty in use, and twenty under construction. I suppose that the small locomotives under construction are accordingly now in use; on the other hand, those which were already in use have now done longer work and I therefore think that this administration could give us interesting supplementary information.

Mr. Papp, Hungarian State Railway. (In German.) — The Hungarian State Railway has motor cars of different kinds in use since 1904. There are 30 two-axle cars, with boiler and de Dion motor; then 6 cars with two and with three axles, either of the same type or petrol-electric cars, and these are used on narrow-gauge lines; and finally, 7 three-axle cars of the Stoltz type, for standard-gauge lines; 6 others have just been delivered and are not yet in use. In addition we have 7 four-axle standard-gauge cars with a more powerful de Dion motor; 4 petrol-electric cars from the firm Weitzer of Arad, also standard-gauge, and 1 Komarek car which is at present being equipped with a Kittel boiler. Then we have 2 small Bavarian locomotives, on the Maffei system, and 25 locomotives with Brotan boiler and with the superheater of the type used on the Hungarian State Railway. With 22 compound two-axle locomotives of an older type, this makes altogether 110 vehicles for motor-car and other similar services. The two-axle motor cars take 40 and the four-axle cars 96 passengers. The average weight of the two-axle cars, passengers included, is 20 tons, and that of the four-axle cars is 37 tons. The small locomotives weigh, in running order, about 20 tons. The motor cars are intended to make annual mileages of 30,000 to 35,000 train-kilometres (18,600 to 21,750 train-miles); actually they make sometimes up to 40,000 train-kilometres (24,850 train-miles). The cost of traction per kilometre, including the train staff, is 26 pfennige (5·02*d.* per mile) with the steam cars, 36 pfennige (6·95*d.*) with the Stoltz cars and 32 pfennige (6·18*d.*) with the petrol-electric car. The cost of upkeep is not included.

I very much regret that Mr. Greppi received no information from us. Either the list of questions did not reach us, or the answer went astray.

The President. (In German.) — Do the working expenses given by Mr. Papp include interest on capital outlay.

Mr. Papp. (In German.) — No.

Mr. Koechlin, French Northern Railway. (In French.) — Mr. President, I note that in the list of French railways using motor cars the French Northern railway is not mentioned. This railway has, however, at present some ten of these cars in use, and it is even exhibiting one at Brussels. If I address the meeting, it is because I wish to tell those of our colleagues who will visit that exhibition that we are very ready to supply them with any information about these cars, which they may desire. The car exhibited is in the French section next to the rolling stock of the French Northern Railway.

The motor car in question is interesting

because it consists of three parts and is reversible, or rather it can run in both directions. The engine is placed between two carriages, one being pushed and the other pulled, so that at the terminus the driver has only to pass from the post of control in one corner of the cab to the post of control in the opposite corner, in order to drive his engine. Each of the parts of the car has a body slightly out of line, that is to say, the body is rather smaller than the loading gauge and is placed a little towards one side, so that the driver has a clear outlook from each of the positions he has to take. Hence, it is unnecessary to turn the car, and this is a very important point. Those of our colleagues who go to Paris can see these cars running between Paris and St. Denis stations; they are every day used for a shuttle service on the Paris Ceinture Railway.

If my memory is correct, these cars weigh about 45 tons with all their gear. The central motor weighs 20 tons; it only includes a small boiler of the ordinary locomotive type. The engine is of the ordinary type with driving axles and the cabin contains two posts of control.

As I said at the start, the railway posesses some ten of these locomotives which are used on different parts of its system.

Mr. Reverdin, *secretary-reporter*. (In German.) — Mr. Vas, inspector-general of the Arad-Csanad Railway, in Hungary, whose general manager, Mr. de Fabry, has not yet arrived in Berne, has requested me to give you some information about the use made of motor cars by that railway.

The lines of that railway are altogether over 460 kilometres (285 miles) in length; of these 70 kilometres (43·5 miles) are narrow-gauge and the rest standard-gauge lines. This railway has since 1902 been using vehicles with motors of different systems, and also special locomotives. It has 12 special cars in use on narrow-gauge lines; there are 8 Ganz steam cars, 1 benzene car, 2 steam locomotives and 1 benzene locomotive with electric motors. On standard-gauge lines it has 41 motor cars in use; there are 4 Ganz steam cars, 1 Daimler benzene car and 36 benzene cars with electric motors, most of them equipped by the Westinghouse Company; 22 of these cars are of 40 horse-power, 14 are of 70 horse-power. Most of these cars have two axles and weigh 13 to 16 tons when empty. Their running speed is from 30 to 60 kilometres (from 18·6 to 37·3 miles) per hour; as a rule they haul two or three trailers. The most powerful cars, those of 70 horse-power, are specially used for an express service. They haul two to three trailers, the gradients not exceeding 6 per mil. They take 25 to 40 passengers and run 200 to 300 kilometres (124 to 186 miles) without taking in supplies. As regards the number of trains hauled in the different ways, there are 12,000 trains with locomotives and 18,000 motor-car trains; accordingly these represent 60 per cent of the total. There are about 40 motor-car trains per day, on the whole system. The annual mileage of a locomotive as a rule attains 28,000 to 30,000 kilometres (17,400 to 18,600 miles), that of a motor car 35,000 to 40,000 kilometres (21,750 to 24,850 miles). The cars are lifted for inspection every three or even only every six months. The working expenses per kilometre amount in the case of the benzene cars with electric motors to about 35 centimes per kilo-

metre (5·40*d*. per mile). and in that of steam cars to about 82 centimes per kilometre (12·67*d*. per mile). The company states that it is very well satisfied with the last types of its benzene electric cars, which it has had in use since 1905-1906. The first cars of this kind had to be modified slightly in order to give them a little more power. The material increase in the receipts, and especially in the net profits, is attributed by the company to the use of this system since 1906; in fact the net profit in 1903 was 1,600,000 kronen (£66,560) and increased in 1909 to over 2,400,000 kronen (£99,840). It should be mentioned that the receipts which amounted in 1909 to 5,900,000 kronen (£245,440) include 1,900,000 kronen (£79,040) for passenger traffic and 4 million kronen (£166,400) for goods traffic. The goods service is hence of considerable importance fromthe point of view of receipts.

It should be added that the goods service is wholly operated by means of steam locomotives, which also haul every day certain trains known as military trains.

Mr. Lippetz, Russian State Railway. (In German.) — In Europe petrol cars are only used with electric drive; in America there are cars in which the motors drive the axles direct. Consequently, the electric motor is a decided improvement. It would hence be interesting to know how the difficulties of a direct drive have been overcome, as henceforth many countries will think of adopting motor cars and it would be useful to elucidate, more or less completely, the question whether direct drive or the electric drive is to be preferred.

The difficulty of a direct drive of the axles by the motor, as that on steam locomotives, arises from the fact that the internal-combustion motor has less flexibility than the steam engine from the point of view of change of speed. The motor will not work at less than a given number of revolutions per minute; below this limit ignition fails. In order to obtain smooth starting, a special clutch is required. The description given by Mr. Clark does not make it quite clear how this problem is solved in the MacKeen car. He says in fact, if I have understood him correctly, that the driving axle is acted on in two ways : 1° by a chain gear and a friction clutch; 2° a spur gearing (see fig. 6 of the report, which shows a truck with spur wheels); after disengaging the one the other is brought into use.

I will therefore ask the reporter for America several questions :

1° What is the number of revolutions of the motor before the friction clutch is applied for starting?

2° What is the number of revolutions of the motor and of the driving axle, and, consequently, the speed of the car, after the clutch is in use?

3° What is that speed after the release of the clutch?

4° How is starting effected? With or without jerks?

5° Within what limits can the number of revolutions of the motor be varied?

The President. (In German.) — The questions asked by Mr. Lippetz refer to technical details. But would it not be better, in order to save time, that the reporters should give answers to those interested, direct? I propose that we

should keep to the general discussion. (*Approval.*)

Are there any other delegates who wish to give any information?

Mr. Kabodi, Hungarian State Railway. (In German.) — You have been told that there are altogether over 60 motor cars on the Hungarian State Railway. I would supplement the summary which has been given to you of the state of the motor-car question in that country. We have in Hungary a whole narrow-gauge railway system whose working is based above all on the use of motor cars, for the passenger traffic has still to be created and motor cars are peculiarly suitable for this purpose.

The local metre (3 ft. 3 3/8 in.) gauge line, Arad-Hegyaljaer, built in 1907, is operated by means of motor cars exclusively. It has for this purpose 11 petrol-electric cars, with four axles, which work an important passenger traffic. These cars were supplied by the firm Weitzer, of Arad. They contain 50 seats and are accompanied by a four-axle trailer which takes 60 passengers, so that each train can normally carry 110 passengers. The steepest up-gradient on the line is 27 per mil. The motor cars are equipped with a de Dion petrol motor directly coupled with the 45-kilowatt dynamo. The design of the cars is similar to that of the rolling stock on the Arad-Csanad Railway; they have worked irreproachably and have made it possible to meet a continual growth of the traffic. The results correspond with those obtained on the Arad-Csanad Railway, especially as regards working expenses per car-kilometre, which are 32 to 35 heller (5·14*d.* to 5·62*d.* per car-mile). It should, however, be mentioned that the delicate motor mechanism of these cars is subjected to rather considerable wear and tear, and, consequently, the cost of repairs is higher than in the case of small locomotives. Owing to the high cost of upkeep of the motor cars, but more especially also on account of the important passenger traffic developed by the motor-car service, the said narrow-gauge railway has decided to adopt *electric traction*; consequently, the local line in question, which has a length of 54 kilometres (33·5 miles), will soon be electrified.

Mr. Steinbiss. (In German.) — I can give you some supplementary information about the question of trailers. We also have trailers on the Prussian State Railway; they take 50 passengers and weigh 11 to 12 tons when empty, and 18 tons when fully loaded. The train consists of an accumulator car and of a trailer; it weighs 80 to 81 tons and runs at a speed of 25 to 28 kilometres (15·5 to 17·4 miles) on an up-gradient of 8·3 per mil. The distance it can run is about 70 to 80 kilometres (43 to 50 miles). Under such conditions, we have obtained very good results with heavily-loaded trains. What is difficult is the transhipment. The accumulator cars are used without being turned, but they must of course be shunted at the terminal stations if they are running with trailers.

The President. (In German.) — Do you wish to continue the general discussion? I would remark that noon is approaching and that it will accordingly become necessary to adjourn the meeting to this afternoon. It would in my opinion be advis-

able to close the general discussion and to pass this afternoon to the discussion of the conclusions.

Mr. Ernest Gerard, Ministry of railways, Belgium. (In French.) — I should like to make some further remarks in the general discussion.

The President. (In French.) — I call upon you to speak.

Mr. Ernest Gerard. (In French.) — Gentlemen, the conclusions of Mr. Greppi's report are very complete and I think that we can all agree to them, except as regards certain points.

The reporter remarked, at the beginning of his paper, that his list of questions had been sent to seventy-four administrations, forty-three of which answered, and twenty-six stated that they had no motor cars in use, that they never had had any in use and that they had no intention of building any.

Those twenty-six administrations seem to treat the subject lightly, and accordingly I feel compelled to raise my voice against the somewhat cavalier way in which they speak of motor cars.

From the technical point of view, the question of the type of motor car no longer needs discussion, nor does that of the details of the mechanism. All the reports presented this session, as well as those submitted to former sessions, supply sufficient information to enable locomotive and rolling-stock engineers to form a clear idea of the type of motor car or small equivalent locomotive, to be used in attaining the desired object.

In the case in question, a double object is aimed at which can be defined as follows : to have cheap light trains so as to make it possible to multiply them and so promote a supplementary traffic and meet the wishes of the public. Another object consists in replacing heavy trains, with too much accommodation, by better-utilized units.

Thus traction expenses are reduced, the traffic operated is increased, and at the same time wear and tear of the track is reduced. It is a partial transformation of certain lines of a main railroad system into light-railway lines, as regards method of operation.

Now when locomotive and rolling-stock engineers try to carry out this object, at once there is opposition from the traffic employees. The latter do not wish to follow the lead of the former. Station masters prefer big trains, so that they can place an entire compartment at the disposition of a traveller, even if he is the only one who turns up. (*Laughter.*)

It is not technical means which are lacking in order to organize the service; we have electricity, gazolene, motor cars, small locomotives of all kinds.

What then is to be done to bring about some alteration in the present state of affairs? How shake off this apathy? There is only one way. By encouraging the operating department to back up the attempts of the locomotive and rolling stock department.

But there is another enemy to economic operation.

The reporter for the United States has declared that in consequence of the labour legislation passed by Congress and by the legislative bodies of certain states, every train, however short, must have a staff of at least five employees. What is the good,

then, of reducing the rolling stock to what is strictly necessary?

I therefore think that it is advisable, either by means of premiums or otherwise, to encourage the traffic employees, especially the station masters, to second the efforts of the locomotive and rolling-stock department in promoting the use of small locomotives or of motor cars.

Nor must one be too much embarrassed by objections to details concerning the arrangement of the cars, the dimensions of the seats, etc. It is here only a question of trains running only short distances at reduced speeds, and it is evident that an economic service cannot be organized so as to offer the same conditions of comfort as a main-line service.

Locomotive engineers try to realize a saving of 15 to 20 per cent in the fuel by designing improved locomotives, but when it is possible to effect a saving of 40 per cent in the working — and this would be possible — they do not always meet with the necessary assistance from those who have in their hands the organization of the train service.

If it is necessary, in certain cases, to have both types of rolling stock available, one reduces the time any is standing idle by operating the branch line jointly with a busier part of the line. Or else, to follow the example of the Prussian State Railway, one selects, for the concentration of several motor cars, a place where several secondary lines meet, lines generally operated by some of these motor cars, the others serving as reserve. This reserve and ordinary carriages afford at a given moment a supplementary means of forming longer or more numerous trains.

I accordingly have the honour of proposing that the following clauses should be added to Mr. Greppi's conclusions :

" To encourage the staff, in suitable ways, well to utilize either the motor cars, or the trains of limited capacity composed of small locomotives and light carriages.

" Whether the attempts made by locomotive and rolling-stock engineers are wasted or not depends on this staff, and hence they can obtain from their traffic colleagues valuable assistance in attaining this important economic object." (*Applause.*)

The President. (In German.) — Later on we will read out the exact wording of the proposition just brought forward. In several quarters the wish has been expressed that the conclusions should be discussed at the morning meeting. That would only be possible if few amendments were proposed. I will leave it to you to decide whether you will examine the conclusions now already or postpone this examination to the afternoon. Subject to your consent, I am of opinion that it would be advisable to start with the conclusions this morning. We can shorten the discussion if, instead of reading out the conclusions, I ask in the case of each clause, what amendments are proposed.

The general discussion is accordingly closed and we pass on to the examination of the conclusions, the first of which runs as follows :

" 1° Automotor cars can be used in certain cases for economic services, in order to facilitate local communication at a moderate outlay, provided that the traffic conditions lend themselves to the organization of trains, carrying a regular traffic or at least one which only varies rarely

and but little, that the line is an easy one and that the goods traffic can be carried conveniently and completely on separate trains."

— Adopted.

" 2° The power of the motors of the automotor cars should present a certain margin beyond the ordinary work, so that it is possible to cope with variations of the traffic within certain ascertained limits."

— Adopted.

" 3° It would be desirable to make it possible to utilize the car independently of the motor by having either separate motor trucks, or some other device making it possible to remove and replace the mechanical part easily."

— Adopted.

" 4° From the point of view of economy of staff, that is to say, having only one traction agent, accumulator or petrol cars seem the most suitable. The types used by the administrations which have given me information represent units of too low a power. It would be desirable that investigations should be made in order to increase this power suitably, and to ensure easy and inexpensive maintenance."

Mr. Greppi, *reporter*. (In French.) — Clause 4 should be modified. In fact we now know that petrol cars of considerable power are used in America and Hungary.

I therefore propose to say :

" 4° From the point of view of economy of staff, that is to say, having only one traction agent, accumulator or petrol cars seem the most suitable. It would be desirable that the investigations should be continued in order to ensure simple design and easy and inexpensive maintenance."

— Clause 4, as amended by Mr. Greppi, is then adopted.

The President. (In French.) — " 5° As regards steam cars, it would be desirable to reduce to a minimum the care required for the boiler, and in particular to improve the semi-automatic feeding of the grate or to improve the methods of using liquid fuel."

— Adopted.

" 6° It would be desirable to recommend the investigation of small locomotives able to replace automotor cars, with the advantage of greater independence. The luggage-van locomotives, or the motor luggage-vans, represent an intermediate solution, which it seems can be suitably applied in certain cases."

— Adopted.

The President. (In French.) — We now have to decide about Mr. Gerard's proposition, which runs as follows :

" To encourage the staff, in suitable ways, well to utilize either the motor cars, or the trains of limited capacity composed of small locomotives and light carriages.

" Whether the attempts made by locomotive and rolling-stock engineers are wasted or not depends on this staff, and hence they can obtain from their traffic colleagues valuable assistance in attaining this important economic object."

Mr. de Burlet, Belgian National Sub-

urban Railway. (In French.) — I regret that I do not agree with my Belgian colleague, Mr. Gerard. It is in fact impossible for me to accept this proposition, which evidently throws a reflection on the traffic service. Such a criticism is out of place among the conclusions of an international congress; whether it be well founded or not, is a question I will not even consider.

If Mr. Gerard absolutely desires to add a clause to Mr. Greppi's conclusions, he should aim at the whole administration of the railways; not only at the traffic department, but also at the other branches of the service : locomotive and rolling stock, way and works, etc. All these services must make joint efforts in order to ensure the utilization of motor cars under the best possible conditions.

Moreover, it seems to me to be unnecessary to say so. When the Congress expresses wishes in favour of the development of a system already adopted by several administrations, is it really useful to add that railway administrations should be encouraged to investigate it and adopt it in their turn?

Consequently, if Mr. Gerard's proposition is retained, it must in any case be modified radically. (*Approval.*)

I am president of the board of the Belgian National Suburban Railway Company, and I do not desire that it should some day be possible to read in our proceedings that I have assisted in voting a conclusion which has the object of encouraging — I will not say admonishing — one of the branches of the administration of the Belgian State Railway.

Mr. Ernest Gerard. (In French.) — I by no means oppose the modification of the text which I have proposed. I must, however, observe that it is just as justifiable as for instance a text stating that drivers should receive premiums for economies in fuel and oil.

However this may be, my proposition implies no criticism of the traffic employees, but I think that these should be encouraged, either by premiums or otherwise. Why should one not do for such employees what one does in the case of drivers who receive coal and oil premiums?

We must be precise in our conclusions and not remain vague. That is the reason why I brougbt forward this proposal which has no other object but the object of economy.

Mr. de Burlet. (In French.) — I cannot say that I am satisfied with Mr. Gerard's explanations and I persist in opposing the adoption of his proposition. The Congress should limit itself to recording the results of experience acquired. This is what the reporters generally have done and the railway administrations must be left to act without marking out especially what services are to be encouraged.

Mr. Gerard has just declared that the text proposed does not imply any criticism. I accept his statement very willingly, but he will recognize that in reading his resolution carefully, this error is possible, for the request is " to encourage the staff, in " suitable ways, well to utilize either the " motor cars, or the trains of limited " capacity, *for it depends on this staff* " whether the attempts made by the loco- " motive engineers are wasted or not, and " hence they can obtain from their traffic " colleagues valuable assistance..."

Only, if this text does not imply a criticism — and I am delighted to hear it — I wonder what is its meaning and what is its use? I therefore propose that it should be rejected. Every troublesome interpretation is to be avoided.

Mr. Ernest Gerard. (In French.) — Allow me to say two words to justify the text I have proposed.

Of seventy-four administrations consulted by Mr. Greppi, forty-three sent answers. Of these forty-three, twenty-six stated that they had no motor car or equivalent small locomotive in use, that they never had any in use and had no intention of building any.

Mr. de Burlet. (In French.) — Is that the fault of the traffic department?

Mr. Ernest Gerard. (In French.) — Efforts have been made to develop an economic service. If they have failed, it is because one does not sufficiently encourage the good utilization of motor cars and of light trains.

As I have just stated, economic working could easily be developed, particularly on very busy days at places where several small lines meet.

Mr. Mauris, Paris-Lyons-Mediterranean Railway. (In French.) — I support the remarks made by Mr. de Burlet. When a question has been fully considered by a company, it is necessary that its whole staff should help towards the production of a good service. The contrary would be inadmissible.

A service cannot oppose measures which have been decided to be advisable, and a conclusion similar to that of Mr. Gerard would be a reflection on the traffic employees. The Congress hence cannot accept it.

Mr. Gerard has just stated that some administrations look upon the use of motor cars, with indifference. If such is their attitude, it is because conditions are unfavourable. The experiment made by the Paris-Lyons-Mediterranean Railway with twenty cars did not give good results, and this railway has ceased to try to develop this system of working.

We have distributed these cars among a number of minor lines while it should have been possible to group them at certain junction points where there would have been a chance of utilizing them better and of arranging for their use as reserves.

This is a question of kind, and in each case we must consider the conditions special to the district when introducing economic services.

Mr. Greppi, *reporter.* (In French.) — If many administrations have answered to the list of questions that they had no motor car in use and had no intention of building any, this is not due to ill-will on the part of the traffic employees, but because their conditions are not favourable for the proper application of the system.

The Arad-Csanad Railway, for instance, certainly is under conditions favourable for the proper utilization of a proper number of motor cars, superior even to that of locomotives, while with us it would be difficult to use more than 100 motor cars to 4,500 locomotives.

It is true that in some cases difficulties are made by certain station masters who have always been accustomed to have

their complete trains, and who show but little desire to use motor cars.

However this may be, this is a question of a detail easy to solve, and it is useless to allude to it in the conclusions.

Mr. Gerstner. (In German.) — I ask that the discussion should be closed.

The President. (In German.) — If we do not find a wording which will satisfy everybody it is preferable to abstain, remembering the Belgian motto : " *L'union fait la force* ". (*Laughter.*)

Mr. de Burlet. (In French.) — Very well, Mr. President. Let us abstain from any wording which might be equivocal.

Mr. Ernest Gerard. (In French.) — From the technical point of view, the question is solved, but the same does not apply to the utilization of motor cars. This is what should be encouraged, whether by premiums or otherwise, as is done in Prussia and elsewhere.

The President. (In French.) — I remember that Mr. Belpaire had the great merit of having recommended and introduced motor-car traction, and I perfectly understand that in this respect the Belgian State Railway has greater experience than the administration of railways in other countries. But, on the other hand, trials having been made and given up, the Congress cannot in principle assert its will; it must limit itself to enlightening all administrations while leaving them free to select what suits them best under their individual conditions.

The last wording which Mr. Gerard has handed to me speaks of the efforts to be made in order to utilize motor cars.

Mr. Ernest Gerard. (In French.) — I have just now quoted Prussia which places its motor cars at given points. Thus there are ways of utilizing them.

It must not be asserted, as a general statement, that they cannot be utilized, for this would be an error. If it is stated that certain administrations have succeeded in utilizing motor cars well by placing them at points where several small branches meet, it would be advisable to mention this in a conclusion, which would then be well-timed.

Mr. de Burlet. (In French.) — That is stated in the report.

Mr. Mauris. (In French.) — The reports mention various systems. In the trials different systems have been applied and consequently it cannot be said that the technical problem is actually solved. There are several systems to choose from.

Mr. Ernest Gerard. (In French.) — It is true that one has the trouble of choosing between different systems, but there will always be one more suitable for adoption than the others.

The President. (In French.) — Mr. Greppi's conclusions which we have just adopted recommend that investigations should be continued. These are not yet concluded and, hence, it is not expedient to draw a conclusion from them.

Mr. Ernest Gerard. (In French.) — I think that methods for utilizing motor cars exist which can ensure success, and one of these methods is to go in for special methods of encouragement which it is

advisable to adopt when economy is aimed at.

The President. (In French.) — It seems impossible to find a wording which will satisfy everybody, and accordingly we can only pass it over.

Mr. Ernest Gerard. (In French.)— Could not the bureau find a basis for an agreement? If not, I do not insist.

The President. (In French.) — I think that it is not the intention of the majority of the meeting to adopt a conclusion in the direction recommended by Mr. Gerard. (*Approval.*)

It shall accordingly be so.

Meeting held on 9 July, 1910 (morning).

Communication made by the Bureau.

The President. (In French.) — Mr. Doniol, inspector-general of bridges and roads (retired), has presented to the section a certain number of pamphlets concerning continuous-propulsion motor-car trains.

As this refers to a question which we have already dealt with, jointly with the 2nd and 5th sections, the rules do not allow us to return to it. As however the author of that pamphlet is of opinion that it is advisable to place the subject on the agenda of the next session, we will mention it in the minutes. In this way it will be brought to the notice of the Permanent Commission.

In the meantime Mr. Doniol has expressed the wish that the members of the 3rd section should obtain his pamphlet; he has deposited a number of copies of it in the office of the general secretary.

Gentlemen, we have concluded our agenda. Before we separate, allow me to thank you once more for the confidence you have kindly shown in me in asking me to preside over your labours. I have tried to direct them very impartially so as to render them profitable to all concerned. (*Applause.*)

DISCUSSION AT THE GENERAL MEETING

Meeting held on 15 July, 1910 (morning).

MR. P. WEISSENBACH, PRESIDENT, IN THE CHAIR.
GENERAL SECRETARY : MR. L. WEISSENBRUCH.
FIRST ASSISTANT GENERAL SECRETARY : MR. MÜRSET.
SECOND ASSISTANT GENERAL SECRETARY : DR. A. BONZON.

Mr. Dietler, *president of the 3rd section*, read the

Report of the 2nd, 3rd and 5th sections meeting jointly.

(See *Journal de la huitième session*, No. 5, p. 11.)

" Mr. C. Peter CLARK gave a summary of his report. He added some further information about the use of motor cars in America, which had shown some increase quite recently. It had been recognized that this system of traction could be useful on secondary lines, and also for increasing the service on main lines. The use of such cars had been experimented with, and some companies had ordered a certain number of them after trials. The motor cars used were driven by steam, with coal or oil as fuel, or by gasolene with direct mechanical transmission, or by gasolene with electric motors. Since the issue of the report seventy-five cars of the second and thirteen cars of the third type had been ordered. The question still unsettled as to the superiority of either system was whether the benefit of electric control would justify the additional weight and cost.

" Mr. GREPPI gave a summary of his report. He stated that out of forty-three administrations who sent answers to his list of questions, only thirteen actually used motor cars. These were 195 in number, 185 of which were steam cars. Some other systems had been tried.

" Small economic locomotives had also been constructed, with grates fed automatically, which had given good results.

" The maintenance of these vehicles was in general considered to be troublesome.

" Mr. Greppi added that he would be pleased to have some information from the Prussian, Hungarian and Bavarian railways about the results they had obtained with the different systems in use.

" The President requested the administrations who had any further information to give it kindly before they proceeded to the discussion of the conclusions.

" Mr. Steinbiss (*Prussian State Railway*) stated that his administration had in use 100 accumulator cars, accommodating up to 130 passengers per car. They were constructed as double cars and ran at 60 kilometres (37·3 miles) per hour. They weighed 54·5 tons (53·6 English tons) empty and 63 tons (62 English tons) loaded, and could haul a trailer weighing 18 tons (17·7 English tons) up gradients of 20 per mil. These cars ran 50,000 kilometres (31,000 miles) per year.

" The cost of operation amounted to from 45 to 65 pfennige per train-kilometre (7*d.* to 10*d.* per train-mile), including amortization of power installations. They were run by a driver and a conductor.

" Mr. Papp (*Hungarian State Railway*) used altogether 110 motor cars and special locomotives.

" The cars had room for from 40 to 96 passengers. They weighed from 20 to 37 tons (19·7 to 36·4 English tons) and ran up to 40,000 kilometres (24,850 miles) per year.

" The locomotives weighed 20 tons (19·7 English tons) and ran from 30,000 to 40,000 kilometres (18,600 to 24,850 miles) per year. The cost of operation amounted to from 36 to 42 centimes for the steam cars and to 36 centimes for the petrol-electric cars, per train-kilometre (respectively from 5·56*d.* to 6·49*d.* and 5·56*d.* per train-mile).

" Mr. Koechlin (*French Northern Railway*) stated that his company had ten steam cars in use. The engine was in the middle and the cars could run in either direction. It weighs 45 tons (44·3 English tons). One of these cars was then at the Brussels exhibition.

" Mr. Vas (*Arad & Csanad Railway, Hungary*) gave some information about the motor-car services of his company. It had fifty motor cars and three locomotives, for narrow-gauge and standard-gauge lines. More especially, the thirty-six petrol-electric cars which it owned gave every satisfaction. They were used with trailers for the express service and the ordinary service between Szegedin, Arad and Brod. The cost of operation of these cars amounted to 35 centimes per train-kilometre (5·41*d.* per train-mile); it amounted to 82 centimes (1*s.* 0·67*d.* per train-mile) in the case of the steam cars, of which a dozen were also in use.

" The company attributed the increase in their receipts, which had become particularly marked since 1906, to the introduction of motor cars.

" Mr. Lippetz (*Russian State Railway*) asked whether any technical information could be given as to the system for change of speeds adopted on the cars mentioned by Mr. C. Peter Clark.

" The President requested that the discussion should remain general; any technical details could be supplied individually to those desirous of having it.

" Mr. Kabodi (*Hungarian State Railway*) stated that on the Arad-Hegyaljaer line, 54 kilometres (33·5 miles) in length, with a gauge of 1 metre (3 ft. 3 $^3/_8$ in.), eleven petrol-electric cars were used, having four axles, holding fifty passengers and

*

hauling a trailer on gradients of up to 27 per mil.

" The cost of operation varied from 33·3 to 36·4 centimes per train-kilometre (5·14*d.* to 5·62*d.* per train-mile).

" The system had resulted in a great increase in the number of passengers.

" Mr. Ernest Gerard (*Belgian government*) was surprised to find that according to Mr. Greppi's report a large number of railways had declared that they had no motor-cars in use and did not propose to try any. He attributed this to a certain hesitation, perhaps on the part of the traffic department. Conclusive results had been obtained from the technical point of view and it was a question of utilizing these properly. He desired that a final conclusion should be added, to express that the traffic department should second the efforts of the locomotive and rolling stock department in order to obtain the economic results which might be expected from motor-cars.

" Mr. de Burlet (*Belgian National Suburban Railway*) opposed this wish, as it seemed to him to express an unjustifiable criticism of the traffic departments.

" Mr. Mauris (*Paris-Lyons-Mediterranean Railway*) agreed with Mr. de Burlet and said that one had to consider in each individual case the particular conditions of the railway system before introducing such services.

" Mr. Greppi (*reporter*) also thought that the administrations which had sent negative answers might have special reasons against the use of motor-cars.

" Mr. Ernest Gerard observed that certain countries, for instance Prussia, had succeeded in working out systems for utilizing motor-cars well, so as to obtain the best economic results.

" The President then proposed the discussion of Mr. Greppi's conclusions.

" Mr. Greppi, in consequence of the information which had been supplied to the meeting, proposed to modify conclusion 4° as follows :

" 4° From the point of view of economy of staff, that is to say, having only one traction agent, accumulator or petrol cars seem the most suitable. It would be desirable that the investigations should be continued in order to ensure simple design and easy and inexpensive maintenance."

" Mr. Greppi's proposed conclusions were then adopted, for submission to the general meeting, in the following form :

The President. — The following are the

CONCLUSIONS.

" 1° Automotor cars can be used in cer-
" tain cases for economic services, in or-
" der to facilitate local communication at
" a moderate outlay, provided that the
" traffic conditions lend themselves to the
" organization of trains, carrying a re-
" gular traffic or at least one which only
" varies rarely and but little, that the line
" is an easy one and that the goods traffic
" can be carried conveniently and com-
" pletely on separate trains.

" 2° The power of the motors of the
" automotor cars should present a certain
" margin beyond the ordinary work, so

" that it is possible to cope with variations " of the traffic within certain ascertained " limits.

" 3° It would be desirable to make it " possible to utilize the car independently " of the motor by having either separate " motor trucks, or some other device " making it possible to remove and re- " place the mechanical part easily.

" 4° From the point of view of economy " of staff, that is to say, having only one " traction agent, accumulator or petrol " cars seem the most suitable. It would be " desirable that the investigations should " be continued in order to ensure simple " design and easy and inexpensive main- " tenance.

" 5° As regards steam cars, it would be " desirable to reduce to a minimum the " care required for the boiler and in par- " ticular to improve the semi-automatic " feeding of the grate or to improve the " methods of using liquid fuel.

" 6° It would be desirable to recom- " mend the investigation of small locomo- " tives able to replace automotor cars, with " the advantage of greater independence. " The luggage-van locomotives, or the " motor luggage-vans, represent an inter- " mediate solution, which it seems can be " suitably applied in certain cases."

— The conclusions were confirmed by the general meeting.

4TH SECTION — GENERAL

OPENING MEETING

4 July 1910, at 4.50 p. m.

PROVISIONAL PRESIDENT, MR. WEISSENBACH,
MEMBER OF THE PERMANENT COMMISSION OF THE CONGRESS.

The President. (In French.) — Gentlemen, the Permanent Commission has asked me to preside while we appoint the bureau of the 4th section.

I propose that we should appoint as our president Mr. C. COLSON, member of the Institute, inspector-general of bridges and roads, State councillor of France, and member of the Permanent Commission of the Congress, whose profound knowledge of railway matters is known to all of you. (*Unanimous approval and applause.*)

I also propose to you to appoint the following :

1° As vice-presidents : Mr. Evelyn CECIL, member of Parliament (England), director of the London & South Western Railway and member of the Permanent Commission of the Congress; Mr. J. V. Mendes GUERREIRO, engineer, inspector-general of bridges and roads of Portugal and member of the Permanent Commission of the Congress; Mr. Fairfax HARRISON, vice-president of the Southern Railway (United States of America) and member of the Permanent Commission of the Congress; and Mr. V. TIMONOFF, privy councillor, professor, engineer of ways of communication, engineer of bridges and roads, manager of the statistical department of the Russian ministry of ways of communication. (*Applause.*)

2° As principal secretary : Mr. BLOCH, chief engineer, assistant traffic manager of the Orleans Railway of France. (*Applause.*)

— Mr. WEISSENBACH vacated the chair which was then occupied by Mr. COLSON, who thanked the meeting for honouring him by calling upon him to preside over their labours. (*Applause.*)

— On the proposal of the president, the SECTION then appointed the other members of the bureau and drew up provisional agenda.

SECTION IV : GENERAL

[383 .2]

QUESTION XIII

RAILWAYS AND WATERWAYS

The investigation of the influence of waterways considered as feeders and as competitors, on railways.

Reporters :

Great Britain. — Mr. G. R. Jebb, M. Inst. C. E., member of the council of the Institution of civil engineers, chief engineer of the Shropshire Union Railways and Canal Company and of the Birmingham canal navigations.

America. — Mr. William E. Hoyt, member American Society of civil engineers, special engineer, New York Central Lines.

Other Countries. — Mr. C. Colson, general inspector of bridges and roads, State Concillor of France, and Mr. Louis Marlio, engineer of bridges and roads.

[385 .2]

REPORT N° 1

(Great Britain)

By G. R. JEBB, M. Inst. C. E.,

MEMBER OF THE COUNCIL OF THE INSTITUTION OF CIVIL ENGINEERS,
CHIEF ENGINEER OF THE SHROPSHIRE UNION RAILWAYS AND CANAL COMPANY
AND OF THE BIRMINGHAM CANAL NAVIGATIONS.

Great Britain and Ireland.

To enable me to compile this paper, the general secretary of the Congress Mr. Weissenbruch, kindly issued at my request, a list of questions, bearing on the question, twenty-two in number (see appendix), to forty-one railway companies in the United Kingdom of Great Britain and Ireland, of which twenty have replied, and it appears from the replies received that the influence of waterways, considered as feeders, on railways is negligible except in the case of the Birmingham Canal Navigations.

This canal system is of such an exceptional character that I will give a short description of it and its influence on railways.

The Birmingham Canal system is a network of canals chiefly in the mining districts of South Staffordshire known as the black country, but extending into Warwickshire and Worcestershire and its character is in many ways unique.

The total length is about 159 miles exclusive of some 550 private basins and short branches. The Canal Company do not act as carriers.

Works of almost all descriptions such as ironworks, mills, forges, brickworks, collieries, chain and anchor works, nail works, tube works, galvanizing works, chemical works, have been built from time to time on the banks of the canal and

*

these works form almost a continuous line for many miles between Birmingham, Wolverhampton and other places.

A large number of seams of coal are being worked under and near the canal — (one of them 30 feet in thickness), in consequence of which the canal and works often subside from 15 to 20 feet and in some places as much as 30 feet — nearly the whole area between Birmingham and Wolverhampton and in the neighbourhood of Dudley is honeycombed by coal workings.

A large number of the works on the banks of the canal have no direct railway communication, in consequence of which, twenty-six railway basins, or places for the direct transhipment of goods from boats on the canal to trucks on railway sidings, and *vice versa* have been made.

These railway basins are of great advantage to the railway companies, as they shorten the distance traffic has to be boated to and from the railway.

Railway basins have been constructed by the following railway companies *viz.* :

The Great Western Railway Company;
The London & North Western Railway Company;
The Midland Railway Company.

In many cases, the railway companies have made private lines to the basins and constructed warehouses, sheds, cranes, etc., for the accommodation of traffic. The Birmingham Canal may, therefore, be considered as a valuable feeder to the railway companies; it is also a competitor, but chiefly for short distances and principally for the conveyance of coal and bricks.

The total amount of traffic interchanged between the above mentioned railways and the Birmingham Canal is on an average about 1,202,400 tons per annum.

The annual traffic on the canal is roughly 8,000,000 tons or about two ninths of the total traffic of all inland navigations of the United Kingdom of Great Britain, of this 8 million tons about one half is coal, about four fifths of which goes to works on the banks of the canal itself, an average distance of something like 8 miles.

Of the forty-one railway companies in the United Kingdom of Great Britain and Ireland about one sixth of them have inland waterways to compete with for traffic the more important being.

1° *The London & North Western Railway Company*, the canals competing being as follows :

The Lancaster Canal, Huddersfield Canal, Ashton Canal, St. Helens Canal, Shropshire Union Railways and Canal, Birmingham Canal Navigations, Manchester Ship Canal, Manchester Ship Canal (Bridgewater Undertaking), Leeds & Liverpool Canal, Weaver Navigation, Trent & Mersey Navigation, Macclesfield Canal, Staffordshire & Worcestershire Canal, Coventry Canal, Warwick & Birmingham Canal, Warwick & Napton Canal, Oxford Canal and Grand Junction Canal.

2° *The Great Western Railway Company :*

The River Thames & Kennet & Avon Canal, Wiltshire & Berkshire Canal, Oxford Canal, Grand Junction Canal, Gloucester & Berkley Canal, Severn Navigation, Lower Avon Navigation, Staffordshire & Worcestershire Canal, Worcester & Birmingham Canal, Stourbridge Canal, Birmingham Canal Navigations, Stratford-on-Avon Canal, Shropshire Union Railways & Canal Company, Bridgewater & Taunton Canal, Grand Western Canal, Brecon & Abergavenny & Monmouthshire Canals, Swansea Tennant & Neath Canals and Glamorgan & Aberdare Canals.

3° *The Midland Railway Company :*

The Warwick & Birmingham Canal, Birmingham & Warwick Junction Canal, Birmingham Canal Navigations, Sharpness New Docks & Gloucester & Birmingham Navigation, Trent & Mersey Canal, Trent Navigation, Ashby Canal, Coventry Canal, Cromford Canal, Chesterfield Canal, River Severn Navigations, Lydney Canal and Nottingham Canal.

4° *The Lancashire & Yorkshire Railway Company :*

The Leeds & Liverpool Canal, Bridgewater Canal, Aire & Calder Navigation, Calder & Hebble Navigation, Rochdale Canal, Manchester Ship Canal, Barnsley Canal, Sheffield & South Yorkshire Canal, Douglas Navigation, Manchester Bury & Bolton Canal, Ashton Canal, Peak Forest Canal, Macclesfield Canal and Chesterfield Canal.

There are 177 canal systems in the United Kingdom representing a length of about 4,673 miles, of these 46, (1,114 miles) are either owned, or more or less controlled, by railway companies, the most important being :

The London & North Western Railway Company, who own or practically control the Lancaster, Huddersfield, St. Helens, Shropshire Union and Birmingham Canals.

The Great Western Railway Company :

The Kennet & Avon, Stratford-on-Avon, Bridgewater & Taunton, Grand Western, Brecon & Abergavenny & Monmouthshire, Swansea and Stourbridge Extension Canals.

The Midland Railway Company :

The Ashby and Cromford Canals.

The Great Central Railway Company :

The Ashton, Peak Forest, Macclesfield & Chesterfield and Sheffield & South Yorkshire Canals.

The Great Northern Railway Company :

The Grantham & Nottingham Canals and River Witham Navigation.

The Lancashire & Yorkshire Railway Company :

The Manchester Bury & Bolton Canal and Branches.

The North Eastern Railway Company :

The Pocklington Canal & River Ure and River Derwent Navigations.

The North Staffordshire Railway Company :

The Trent & Mersey, Caldon Branch, Newcastle Branch, Burslem Branch, Macclesfield Branch and Leek Branch Canals.

The Caledonian Railway Company :

The Firth & Clyde Navigation.

The North British Railway Company :

The Monkland Canal.

The Midland Great Western Railway of Ireland Company :

The Royal Canal.

Canals and waterways compete for traffic with the railways companies between London, Liverpool, Leeds, Bristol, Goole and the Midland Counties of England, East and West Coast of Scotland, Waterford, Dublin and Limerick, the majority of them are toll takers only, in a few cases the owners act as carriers as well as toll takers *viz.* :

The Manchester Ship Canal (Bridgewater Undertaking), Shropshire Union Railways & Canal, Aire & Calder Navigation, Trent Navigation, Glamorganshire Canal, Leeds & Liverpool Canal, Rochdale Canal, Grantham Canal, Nottingham Canal, Linton Lock Navigation, Trent & Mersey Navigation.

All the railway companies whose opinion has been asked are agreed that, speaking generally, a regular and efficient service is maintained on the waterways, but of course the service is dependent on the traffic which is presented, the service on the waterways is liable more or less to interruption by frost and drought, and on some of the canals this interruption is considerable.

The railway companies have to fix their rates having regard to the competition by the various waterways, and carriers on the canals get as near the rates charged by railway companies as they can between competitive points, but generally speaking,

the rates by canal are lower than by railway; in some cases there are agreed differentials varying in amount.

On the majority of the railways, both collected and delivered and also station to station rates are in operation, which include the services of loading and unloading. The rates for mineral class traffic such as coal, bricks, lime, limestone, etc., are exclusive of these services as well as cartage.

Canal companies and private carriers on canals, in fixing their charges take into account the classification applicable to all canal companies. For heavy traffic, they quote exceptional rates according to circumstances.

Rates by canal are quoted both exclusive and inclusive of loading and unloading according to circumstances and nature of traffic, they also include, if required, storage accommodation at terminal points. Rates are also quoted at owner's risk, as well as at carrier's risk. In some cases, carriers undertake the collection and delivery of traffic and quote inclusive rates for such services.

In cases where canal companies are carriers, they have fixed rates chargeable to all parties alike, but owners of private boats are at liberty to make special bargains for cargoes as they arise without being subject to the Railway and Canal Traffic Acts as regards undue preference.

The greatest load which can be carried in a vessel navigating waterways (with the exception of the Manchester Ship Canal) competing with railways is 250 tons and the smallest 18 tons, but on the bulk of the canals the greatest load may be taken as 25 tons. The motive power used is horse haulage on most of the narrow canals, and steam on the wider canals. Experiments with a view to the adoption of more economical and efficient methods of traction have been conducted on the Birmingham Canal by arranging trains of ten compartment boats each boat carrying about 12 tons and towed by a steam tug and although the cost was found to be considerably less then by horse traction, the obstruction caused at the bends in the canal and at the locks and bridges was so great that this mode of haulage was not adopted.

This method is working satisfactorily on the Aire and Calder Canal where all the circumstances are specially favourable for its use.

Waterways compete for most descriptions of traffic which are usually conveyed on the railways by goods train, but in the main competition is in such traffics as coal, iron, bricks, timber, grain and manure. The canals are equipped with warehouses, cranes, etc., sufficient to meet the requirements of the traffic passing along them, such accommodation in the majority of cases being provided by the canal companies, but in some instances, private canal carriers provide their own warehouses and appliances.

The canals are used for the conveyance of agricultural produce only to a very small extent.

Practically in all cases where the railways compete with the canals, goods collected by the former one day are conveyed and delivered at their destination the

following day, whereas by canal, except for very short distances, transit takes two or more days.

There is a decided tendency for consignments to get smaller every year, traders live more from hand to mouth than formerly, quick despatch of goods is essential as the prevailing method is for traders to keep their stocks as low as possible and often to order their supplies by telegraph or telephone. Between all important towns there is on railways a one day service, and goods collected one day are delivered the next, for example :

London to Birmingham. . .	111 miles.	London to Leeds	186 miles.
— to Manchester . . .	183 —	— to Glasgow	400 —
— to Liverpool. . . .	199 —	— to Dublin	314 —

Speaking generally, the competition between the railways and waterways does not appear to be either increasing or diminishing, and although the competition with the water carriers is in some districts more keen than formerly, the railway companies do not appear to have lost ground.

In the cases of traffic brought by canal carriers to docks for shipment, there is no delay in transferring traffic from barge to ship provided the vessel for which the goods are intended has arrived and is ready to load. In cases of goods received from ship, canal carriers so arrange that their boats are not placed alongside until the vessel is ready to make delivery of the goods thereto, but if they are dealing with small loads to be collected from different vessels, some delay does arise.

Crane power or manual labour is the usual method of transhipment from railway to waterway or *vice versa*, it is impossible to give the cost of transhipment for the various classes of traffic as the services to be performed are so varied. The classes of goods most liable to injury by transhipment are glass, china, earthenware and coal.

With regard to sea competition. Practically all the railways are affected in this respect — traffic is conveyed between all the ports by coasting services — for instances coal and other traffic from South Wales to Liverpool and London and also from the Northern Ports to London, goods from London to Hull and through Hull to towns in Lancashire and Yorkshire *via* the East Coast. London to Liverpool and Manchester, to towns in Lancashire, Cheshire and Yorkshire *via* the West Coast — London, Liverpool, Manchester, Cardiff, Swansea, Bristol and numerous other ports to Scotland.

Speaking generally, the influence of waterways as they exist at the present time, both as competitors and feeders to railways, is not so great as was the case thirty or forty years ago with the exception of the Manchester Ship Canal to which I refer later. Since those times railway freights generally have been lowered, particularly in regard to those commodities which would be likely to pass by a water route.

The railways also give greater facilities for the conveyance of traffic now than was the case many years ago, when the competition with canals was much keener than to-day.

It is probable that if waterways were enlarged and improved and more efficient services were given than at present, it might lead to some reductions in railway rates between points for specific traffic, but this would entirely depend on the extent of the enlargement and improvement.

Manchester Ship Canal :

This canal is of such an important character that I report separately upon its influence on railways.

The Manchester Ship Canal was completed and opened on the 1 January 1894 and is 35 ½ miles in length. It begins at Eastham on the Cheshire Shore of the river Mersey about 6 miles from Liverpool and ends at Manchester.

The ordinary dimensions of the canal are as follows :

Bottom width from Eastham to Barton (30 ½ miles)	120 feet.
— — Barton to Manchester Docks (5 miles)	170 —

The width at water level varies considerably, but the ruling width is as follows :

From Eastham to Barton	200 feet.
— Barton to the Docks	250 —
Depth of water	28 —

Large docks, quays and warehouses have been constructed in Manchester for the accommodation of the largest cargo carrying vessels.

The effect of this Ship Canal as competitors with the railways, is that oversea traffic which if the Ship Canal had not been made would have been landed at Liverpool, Birkenhead, Garston and other ports, thereby giving the railway companies the carriage to Manchester itself and other towns, is now delivered at Manchester by ocean going vessels.

The Ship Canal is also in competition with the London & North Western and other railway routes *via* Holyhead, Fleetwood, Heysham, Liverpool, etc., for Irish traffic to and from Manchester and the surrounding district.

The Ship Canal feeds the railways through Manchester Docks in respect of traffic for inland towns, but the railway companies get less mileage than before the canal was made.

Sea freights from Manchester Docks are invariably the same as to Liverpool, but when landed at the latter port, dock and town dues are levied in addition to the sea and rail freights, and the Ship Canal Company cut their tolls and other charges, so that the total expense through Manchester Docks is never more than if the traffic had been conveyed *via* Liverpool, while in the majority of cases, the expense through Manchester Docks is less.

At the time I write, May 1909, a Royal Commission on canals and waterways in

Great Britain and Ireland is taking evidence on the following subjects which have been referred to it :

1° As to the present condition and financial position of canals and waterways;

2° As to the causes which have operated to prevent the carrying out of improvements by private enterprise, and whether such causes are removable by legislation;

3° As to facilities, improvements and extensions desirable in order to complete a through communication by water between centres of commercial, industrial, or agricultural importance, and between such centres and the sea;

4° As to the prospect of benefit to trade of the countrycompatible with a return on the probable cost; and

5° As to the expediency of canals being made or acquired by public bodies or trusts, and the methods by which funds for the purpose could be obtained or secured; and what should be the system of control and management of such bodies or trusts. The commission was appointed in March 1906.

Representatives of various trades, of County and Borough Councils and other authorities haven given evidence advocating the making of four new main canals from the Midlands near Birmingham to the sea *viz.* :

To the mouths of the rivers Mersey, Severn, Thames and Humber; but however much one witness differed from another, as he did on many important points, in his advocacy of making these canals, all the witnesses agreed that the public could not be depended upon to find the money for such improvements without a guarantee either from the State or from County or Borough Councils. It is clear from the evidence that the object of most of the witnesses was merely to use the improved waterways in an endeavour to bring down railway rates.

Should these four canals to which I have referred be made, I feel sure that no fair return on the capital expended would be possible.

Indian and Colonial Railways.

Of the nine railway companies in the Indian Empire, all of them more or less have river navigation and sea route services to compete with for traffic.

The Southern Mahratta Railway Company, Limited, have the sea route from Mormugo to Bombay.

The Oudh and Rohilkhand Railway, the India General Navigation and Railway Company, Limited, the rivers Ganges, Surjoo and Gogra.

The North Western Railway (Lahore), the native boats on the river Indus chiefly between Multan and Sukkur and places situated on the river between those two points, also the Tuleli Canal which passes close by the City of Hyderabad and through the Country Southwards.

The Madras & Southern Mahratta Railway Company, Limited (Madras Section), Inland Canals between Madras and Coconada.

The East Indian Railway Company & The Eastern Bengal State Railway System. — The India General Navigation and Railway Company, Limited and the Rivers Steam Navigation Company, Limited, whose steamers navigate the rivers Ganges and Bhagirathi.

The India General Navigation and Railway Company, Limited, and the Rivers Steam Navigation Company, Limited, are under the control of the Eastern Bengal State Railway System in respect of the combined services through which through booking arrangements exist, but the railway has no control over their direct services.

The other waterways are not under the control of railway companies.

Waterways compete with railways for traffic between Goalundo and Dibrugarh (Assam), Calcutta, Dighaghat, and Agodghyaghat on the rivers Ganges, Surjoo and Gogra, between Azimgunge and Buxar on the rivers Ganges and Bhagirathi, between certain stations on the Southern Mahratta Railway, and Bombay over the whole section, Madras to Coconada, the sea route from Mormugo to Bombay the Tuleli Canal which runs close by the City of Hyderabad Southwards, chiefly over two of its branches *viz.* :

The Mirwah which passes close by Badin and Nasirwah Eastward through Thar and Parkar District and the sea route Murmugo to Bombay.

The owners of the waterways with the exception of those belonging to the state act as carriers and toll takers.

Native boats as far as is known are exempted from all tolls.

Except in the dry season, there is a regular and efficient service maintained by the waterways. Railway rates, in the majority of cases, have to be adjusted to meet the competition by water and only where the time occupied in transit is of no importance is traffic carried by waterways.

Both collected and delivered and also station to station rates are in operation on the railways.

The rates by railway and waterway are by no means the same, as the steamer companies have quite a separate tariff and charge accordingly. The steamer companies rates are not subject to any statutory control as the railway rates are *viz* : by a schedule of maximum and minimum rates to be charged, which is fixed by government. The rates charged by the steamer companies are invariably lower than the railway rates.

Native boatmen on the return journey to their home stations, rather than work their boats down empty, or wait for better conditions, will carry a cargo for little or no profit, or for merely for an allowance of the grain carried sufficient for their daily food.

In most cases, there is an agreed classification and tariff among the water carriers; freight charges are also fixed by agreement between the owners of goods and the carriers.

In some cases, the rates are at carrier's risk; alternative rates are also quoted at owners risk and are inclusive of loading and unloading and cover the provision of terminal accommodation for a specified period.

The general rule is that traffic for conveyance by water is tendered at and removed from the Water Carriers Depôts.

Special bargains or reductions are made in the rates by the Water Carrying Companies for large quantities, but speaking generally, the same rates are charged to all parties alike, the loads carried vary with the different description of boats, from 2 to 40 tons on the river Indus, from 1 $^{1}/_{2}$ to 6 tons on the Tuleli Canal and up to a 1,000 tons by steamers plying on the rivers Ganges and Bhagirathi, the motive power used on the waterways is steam, sails, oars, propelling poles and punting.

The classes of traffic chiefly competed for by the waterways is salt, betel nut, spices, sulphur, glass, agricultural produce and other miscellaneous articles, but when the water rises in the rivers during the monsoons, they carry grain and seeds in large quantities.

Only in a few cases do the steamer companies provide warehouses and cranes *viz.*: in Calcutta, Bhagalpur, Mormugo and Bombay; at Ajodghyaghat, goods are warehoused in part of the Oudh & Rohilkhand Railway Goods Shed.

The following is a comparison of the time occupied in conveying goods between the undermentioned stations by rail and by steamer during the dry and rainy seasons.

		Dry season.		*Rainy season.*	
	Distance.	Rail.	Steamer.	Rail.	Steamer.
Howrah to Bhagalpur. . . .	265 miles.	3 days.	10 to 13 days.	3 days.	6 days.
— to Dighaghat . . .	344 —	4 —	13 to 15 —	4 —	8 —
— to Patma.	332 —	4 —	13 to 15 —	4 —	8 —

Between Mormugo and Bombay, native boats take eight to ten days for the journey, steamers about two days, the railways less. By water, from Assam to Ajodghyaghat fifteen days and from Calcutta fourteen days, by railway, ten days Assam to Ajodghyaghat and four days from Calcutta to the same place.

The average weight of consignments cannot be determined as they vary considerably.

Competition between railways and waterways is increasing with a few exceptions *viz.*: On the river Indus, chiefly between Multan and Sukkur and on the other waterways in connection therewith where it has steadily decreased for years past. On the rivers Ganges, Surjoo and Gogra, it is increasing, as water carriers are building more steamers.

On the rivers Ganges and Bhagirathi, cargoes are dealt with in flats, which are used as floating warehouses.

These flats are dropped by the steamers at the different depôts and remain there often for several days until they are loaded up. Some of the larger steamers carry cargo on their lower decks, in which case the steamers have to stay at the depôt until the cargo is loaded and unloaded.

To a certain extent the waterways act as feeders to the railways in all classes of goods but chiefly grain and seed.

Traffic is not exchanged between railway and waterway as part of a through route, but in regard to cases where special arrangements are made with the water carriers for combined carriage, traffic is carried through at the combined agreed rates.

Transhipment is performed mostly by manual labour, crane power being provided in a few cases, the cost depends on the distance goods have to be conveyed from waterway to railway and *vice versa*. Goods liable to injury by transhipment are as follows : Iron castings, cast iron railings, casting brass, machinery, glassware and chinaware, cement and cement castings, all goods in liquid condition, also in casks, articles of art pottery and earthenware of all kinds, articles made of clay, tea seeds, stationary, marble or plaster of paris, spirits in jars, billiard tables, butter in tins or casks, etc.

Railway traffic is affected by sea competition to no appreciable extent.

The waterways, as they now exist, interfere only to a slight extent with the earnings of the railways, as although they have taken away some traffic from them, they have brought traffic which the railways would not have had but for the waterways.

It is generally considered that if the waterways were enlarged and improved, considerably more traffic would be diverted from the railways than at present.

New South Wales Government Railways.

The conditions in New South Wales renders competition by the rivers with the railways, comparatively ineffective.

The river courses run long distances, but owing to periodical droughts and the absence of mountain chains from which the rivers might be fed, the duration of navigation is uncertain. The principal districts served by the water carriage offering competition are in the South West and North West, or Hay (South West), 461 miles from Sydney by rail, and Bourke (North West) 509 miles from Sydney by rail.

Western Australia Government Railways.

The only navigable waterway in Western Australia is the Swan river (really an arm of the sea) between Freemantle and Perth a distance of about twelve miles and the waterway is owned and controlled by the Government. Two steamship companies ply for traffic and act as carriers by permit from the Government, but no regular service is maintained, it being entirely dependent upon the shipping, the rates charged are elastic and made to suit special circumstances.

Warehouses and cranes are provided at Perth by the steamship companies, the time occupied in conveyance by river varying according to circumstances, but it does not compare favourably with the railway service. The railway is hardly affected by competition from the steamship companies, and if the Swan river were deepened, Inter-State boats would probably bring cargo to Perth direct, instead of discharging at Freemantle, but this would not materially affect the railway rates.

Tasmanian Government Railways.

In Tasmania, there are no waterways owned privately or by companies, but it is intersected by large rivers.

In some cases, the railway runs along the river banks and along the sea coasts. There is thus water competition in both instances. The railways have also to contend with water competition on the main line which bisects the Island from North to South.

The two principal ports are connected by rail (133 miles) but though the distance by sea is much greater, the competition is effective in the case of goods which do not require quick transit, and special rates have to be quoted to secure such traffic.

Wherever the water competes, the railway rates are made lower than ordinary mileage scale.

From Hobart (the capital) to New Norfolk (26 miles) the railway, road and river run parallel, and there is keen competition for passengers and goods — principally fruit: rail transit being quicker, it takes the major portion of the traffic, but at low rates approximating to those of the steamers. For parcels and small lots of goods, the rail rates include delivery but not collection.

The steamer companies do not deliver beyond the wharves.

Natal Government Railways.

There are no waterways in Natal which compete for traffic against the railways.

APPENDIX.

Detailed list of questions relating to question XIII.

1. Do any waterways compete for traffic with your railway? if so, state the titles of waterways so competing.

2. Are any of the competing waterways under the control of the railway company? if so, state which.

3. Between what points do the waterways compete?

4. *a*) Do the owners of the waterways act as carriers or as toll takers only?
   b) Is there a regular and efficient service maintained by water?
   c) Is service liable to interruption from frost and drought?

5. What is the effect of the competition on railway rates?
   a) Particularly on special large quantities of traffic passing between competitive points when time occupied in transit is of no importance.

6. Are the rates by waterway and railway the same? if not, how do they differ.
   a) Do the rates on your railway include loading, unloading, collection and delivery in the various towns, or are the rates charged for conveyance only from forwarding point to destination?
   b) Is there an agreed classification and tariff amongst the water carriers?
   c) Are the rates by water inclusive or exclusive of loading and unloading? do they cover the provision of terminal accommodation, and are the rates at owner's or carrier's risk?
   d) Do the water carriers undertake the collection and delivery of traffic? if so, are inclusive rates quoted.
   e) Are the same rates charged by water carrying companies to all parties alike for similar goods carried under equal conditions and circumstances, or are special bargains made for quantities as they arise.

7. What is the greatest load which can be carried in a vessel navigating each competing waterway?

8. What is the motive power used on the waterways?
   a) Are any experiments being conducted at the present time with a view to adoption of more economical and efficient methods of traction on the waterways.

9. For what classes of traffic do waterways chiefly compete?
   a) Are the waterways well equipped with up to date terminal facilities, *e. g.* warehouses, cranes, etc., and by whom are these provided?
   b) To what extent are the waterways used for agricultural produce?

10. What is the average time occupied in collecting, conveying, and delivering traffic by waterway and railway respectively between the chief towns and ports on your railway?

11. What is the average weight of each consignment of the more important classes of traffic?

12. Is the tendency for consignments to get smaller?

13. Is quick despatch often essential? If so, give examples.

14. Do you find the competition by waterway is increasing or diminishing?

a) Is the traffic on the waterways in competition with your railways increasing or diminishing?

b) Are road motors taking the traffic from the railways and waterways to any extent?

15. To what extent do vessels have to wait for loading and discharging cargo?

16. Do the waterways act as feeders to the railway? if so, to what extent, and for what classes of traffic?

a) Is traffic exchanged between your railway and the waterways as part of a through route? — if so, is such traffic conveyed at agreed through rates?

17. Describe methods of transhipment.

18. What is the cost of transhipment for various classes of traffic?

19. What classes of traffic are liable to be injured by transhipment?

20. In what respects is your railway affected by sea competition?

21. State generally your views on the influence of waterways as they exist today both as competitors, and feeders, on your railway.

22. What would be the probable effect on your railway rates if the waterways were enlarged and improved?

[385 .2]

REPORT N° 3

(America)

By WILLIAM E. HOYT,
MEMBER AMERICAN SOCIETY OF CIVIL ENGINEERS,
SPECIAL ENGINEER, NEW YORK CENTRAL LINES.

In collecting information relating to the competition of railways and waterways in the United States, I am indebted to Mr. Weissenbruch, the General Secretary of the permanent Commission of the Congress, for material assistance.

Early in March, 1908, at my request, a list of questions was sent by him to the officials of those railroads which were thought to be most affected by the competition of waterways, but, up to the first of October following, only ten replies had been received to the questions submitted.

Mr. Weissenbruch, upon being informed of this, issued another circular letter early in November, 1908, which was sent to the administrative officials of the railroads previously addressed. This letter strongly urged that immediate attention be given to the subject under investigation, and requested that replies be sent at once in order that the work of collecting information should not be delayed.

In answer to this last appeal, only two additional replies were received up to July, 1909.

In consequence of the difficulty of obtaining sufficient data from railroad companies on which to base a report, the writer was obliged to make independent investigations and to have recourse also to material collected by the United States Census, the United States Engineers, together with compilations by Government Commissions containing information relating to the subject.

Briefly summarized, conditions in the United States in reference to railroads and waterways may be described as follows.

Our railroads aggregate in length some 232,000 miles, while there are in operation only 2,190 miles of canals out of a total of 4,500 miles originally constructed.

Seventeen of these canals, having a total length of less than 200 miles, are owned by the United States Government. There are twelve State canals, aggregating 1,360 miles in length, and sixteen private canals, with a total length 632 miles.

The 2,444 miles of canals now abandoned represent an original cost of over $80,000,000.

Rivers.

There are nearly 300 rivers in the United States, used for navigation, and these have a navigable length, in all, of 26,400 miles.

Those tributary to the Atlantic Ocean are approximately 5,300 miles long, while those flowing into the Gulf of Mexico, exclusive of the Mississippi and its tributaries, have approximately the same number of miles navigable.

The Mississipi alone, with its tributaries, has a total of almost 13,900 miles.

Rivers flowing into the Pacific Ocean are 1,600 miles in length, while the Red River of the North, running northerly into Canada, has about 180 miles navigable.

Coast line.

For coastwise transportation, we have in the United States an Atlantic coast line more than 2,000 miles in lenght, and nearly 1,900 miles along the Gulf of Mexico. The Pacific Coast line is upwards of 1,800 miles long, making a grand total of 5,700 miles.

In addition to this, there are extensive ocean-inlet, bay and sound routes with a meandering coast length of over 64,000 miles.

Among these are the Gulf of Maine, Long Island Sound, Delaware Bay and Chesapeake Bay on the Atlantic coast, and Puget Sound on the Pacific coast.

Lakes.

There are also the Great Lakes, which constitute the most extensive and important system of waterways in the world.

These have a United States coast line of nearly 2,800 miles, or, with indentations, a length of over 4,300 miles.

Considering the extent of waterways in the United States, it would seem that they should exert a very considerable influence upon railroad transportation throughout the entire country. We find, however, that there are certain natural limitations and artificial conditions which act as strongly restraining influences in the matter of competition with railways.

Our largest rivers do not flow in the direction of the great traffic movement across

the continent, and there is also a lack of correlation in the various water routes. We find moreover an entire absence of organization in the system of water transportation.

Through freight constitutes, by far, the greater part of the traffic of the country, and this the railroads are well prepared to handle by reason of their thorough standardization und unification, together with the perfection of their rolling-stock.

Our waterways, on the contrary, are widely divided by physical characteristics and handicaped by diversities of floating equipment. Unfortunately too, nearly all the river and canal routes have channels of greatly restricted depth and width, which confine transportation to boats of small capacity.

Another serious limitation is the fact that many of our most important waterways are closed to navigation for approximately five months in the year by ice.

In addition to this, our river channels are continually obstructed by rapidly accumulating deposits of silt, which render inland navigation extremely precarious and uncertain.

In times of drought too, the transportation service is liable to protracted periods of interruption.

Effect of competition.

In estimating the influence of waterways on transportation rates, we find wide differences in the effect of canal, river, ocean and lake competition.

Canals.

In former years, canals were of far greater importance in this respect than at present. Even the Erie Canal, the longest in the United States, has, at present, probably no effect whatever on either local or through rates.

Rivers.

Rivers, on the contrary, have an appreciable influence, depending upon their navigable length, depth and floating equipment. It must be said, however, that only local traffic is seriously affected generally, except in the transportation of coal and lumber, which will be referred to hereafter.

The great lakes.

On the great lakes, we find the effect of water competition to be more marked than on canals or rivers. This is partly due to the length of the routes, the unrestricted depth of water and the excellent harbor facilities, all of which allow the use of large vessels of great tonnage capacity. For this reason, the cost of transportation is small and we find water rates on some classes of commodities so low that the railroads cannot compete with the lake lines.

*

The effect of this has been to force all the important trunk lines of railroads to secure control of lines of vessels on the great lakes in order to stifle competition as much as possible, and, in this, the railroads have been successfull as to most freight, the exceptions being ore, coal and, to somer extent, lumber.

An important result of the great lakes competition is shown in a series of decisions by the United States Supreme Court and the Interstate Commerce Commission, by which railroads are permitted to charge a lower rate to water competitive points than to points not affected by water competition, although the haul may be longer in the former case.

Coast traffic.

The business of water carriers along the coast is very large. There are regular lines of steamships between north Atlantic and south Atlantic ports, as well as coasting steamers running between intermediate ports. Sailing vessels also carry cargoes of considerable size, and there are tramp steamers in addition, which, until recent years, secured an important share of the coastwise traffic; but the business of these apparently is becoming of less importance year by year.

Taken altogether, however, the volume of freight carried by coastwise water lines is of great magnitude, and the rates on bulk commodities, as well as on package freight, to a considerable extent, are so much below railroad rates as to put the railroads practically out of the field, in the way of competition for the greater part of the traffic.

We find also that railroad interests have secured control of important coastwise lines to some extent, so that railroads and water lines are members of traffic associations which make joint rail and water rates, thereby materially reducing the effect of competition.

Details and statistics.

Considering these matters more in detail, it will be possible, in some degree, to ascertain the cause of present conditions in reference to transportation in the United States by means of an analysis of statistics.

In 1889, our railroads carried 429,467,737 tons of freight. During the same year the quantity moved by water in American vessels as reported by the United States Census, amounted to 120,000,000 tons, excluding harbor and raft traffic. In 1906, the raitroads carried 1,610,099,829 tons, while the records show 177,519,758 tons carried by water in the same year.

Over 42 per cent of the water tonnage last named went over the great lakes, and nearly 37 per cent on the Atlantic and Gulf coasts and rivers.

More than half of this tonnage consisted of coal, iron ore and other crude minerals, while lumber and naval stores were next in importance as to quantity.

Third on the list, we find steel rails, pig iron, petroleum, cement, bricks, lime, etc.

Next in bulk, was the group of agricultural products, including grain, flour, fruits, vegetables, cotton and tobacco, these being the most important of all the commodities carried, so far as value is concerned.

The four groups just mentioned comprise 80 per cent of the traffic carried by American vessels. The remaining 20 per cent consists of package and miscellaneous freight which constitutes a large factor in the Atlantic and Gulf coast business by water carriers.

Comparing the above classification with that of the freight carried by railroads in 1906, we find practically the same proportions to obtain.

The Great Lakes.

In the year 1889, the domestic lake traffic was 25,267,000 net tons. In the year 1907, it was more than 80 million tons. Three fourths of the entire lake movement is easterly and southerly.

Iron ore and coal constitute the great bulk of the freight transported over the lakes. In 1907, we find 45 million net tons of iron ore were carried by lake lines, and over 21 million tons of coal, the latter moving westerly and representing about one quarter of the domestic lake traffic.

In 1907, the domestic movement of grain on the lakes was only 150 million bushels, and that of flour only 1,300,000 tons. These figures show a large falling off in recent years due to the decline in export trade.

It is interesting to note that only 5 per cent of the entire lake traffic is carried on to its destination by water after leaving the lakes.

Rivers and canals.

Up to the year 1855, the amount of freight carried by the canals in New York State was more than twice that transported by railroads crossing the state. In 1872, it was only one third, and at the present time, it is less than 3 per cent of that carried by the railroads adjacent thereto.

In 1880, the entire traffic of State and private canals in the United States was 16 million tons. In 1906, it had fallen off the about 6,600,000 tons.

One of the remarkable instances of declining business on waterways is seen in the Mississippi River system, which includes, n addition to the Mississippi itself, the Ohio River, the Missouri, thelllinois, Ouachita, Red and Yazoo Rivers, with all their tributaries, together with a number of other rivers of less importance. The State canals of Illinois and Ohio also are connected with this system, which, in former years, had a very large transportation business.

An index of the decline may be found in statistics of the river tonnage at St. Louis, which is a converging point for traffic of the upper Mississippi, and, to a certain extent, of the lower river also.

In 1890, shipments at St. Louis by steamboats and barges amounted to 601,860 tons. In 1903, they had fallen to 212,207 tons, and in 1904, to 82,565 tons. The following year there was a reduction to 80,575 tons, but in 1906, the shipments rose to 89,185 tons.

Rail shipments, on the contrary, increased in this district from 5 million tons in 1890, to 17 million tons in 1906.

Ohio river and tributaries.

This is, at present, the most important river system in the country as regards traffic.

In 1894, the total movement was 7,795,500 tons. Six years later, this had increased to 14,054,320 tons. In 1904, it had declined to 10,142,550 tons, but in 1905, it rose to 13,163,656 tons, falling again in 1906, to 11,427,784 tons.

Coal from the Pittsburg district and from the extensive fields in West Virginia constitutes an enormous tonnage overt his waterway, and it is due to this commodity that the traffic of the Ohio River system is of such magnitude at present and that there has not been a decided decrease in tonnage as in the case of other inland streams.

Equipment on waterways.

As to the equipment in use on waterways, we find statistics as follows.

The report of the Commissioner of Navigation gives, for the year 1870, the number of steam vessels as 3,524, sailing vessels, 17,534, barges, 1,530, and canal boats, 6,410.

In the year 1907, there were recorded 10,050 steam vessels, 10,866 sailing vessels and 3,264 barges.

More than half the steam vessels now registered are in capacity from 1,000 to 5,000 tons, and a quarter of the steam tonnage is in vessels of over 5,000 tons. Approximately two thirds of the sailing vessels run from 500 to 2,500 tons.

On the coasts and on the great lakes, vessels have greatly increased in size in recent years. On the inland rivers, there has been a considerable decline in steam vessel tonnage, while on the great lakes, sailing vesselsh ave almost disappeared. On the coasts, there are fewer sailing vessels than formerly but they have increased in size.

On western rivers, the large packet steamers have mostly gone out of use, while there has been an increase in the number of small gasoline boats and in the number of barges propelled by towing.

Canal boats are rapidly decreasing in number and in tonnage. The Census Reports for 1889 showed 5,544 canal boats in the United States, with a tonnage of 808,058 tons. In 1907 there were only 731 recorded, with an average tonnage of about 135 tons each.

On the Erie canal, there are now, according to the Bureau of Corporations, less than 450 boats available for transportation.

By the Census Reports, we find an increase in the number of self-propelled vessels in the United States from 5,603 in 1889 to 9,927 in 1906. Three fourths of these however, were small gasoline boats.

The tonnage capacity increase in this time is more marked, showing a rise of 137 per cent, from 1,710,000 tons in 1889, to 4,059,000 tons in 1906.

Among the larger vessels, we find the steamship " Creole „ employed in the Atlantic coasting trade, built in 1907. This is 407 feet long, 53 feet beam, 26 feet deep and registered at 6,387 gross tons. The engines are of the turbine type.

In the Pacific coasting trade, is the " President ", 417 feet long, 44 $^1/_2$ feet beam, 29 feet deep, with a capacity of 5,500 gross tons. Over four hundred passengers can be carried in addition to cargo space. The engines are of 5,000 indicated horse-power.

On the great lakes, there are freight and passenger steamers running regularly, 400 feet in length, and 97 feet wide over all.

One of the largest is the bulk freighter " Thomas F. Cole ", built in 1907. This is 605 feet long, 58 feet beam and 32 feet deep, registered at 7,268 gross tons, with an actual capacity for 12,000 tons of iron ore.

It is apparent that the cost of carriage is reduced generally in proportion to the size of vessels engaged in transportation. On nearly all our rivers and canals, the use of light draft boats is made necessary by reason of shallow and tortuous channels, thereby preventing economy of operation.

Reference has already been made to the wide differences in the physical characteristics of our inland waterways which necessitate corresponding diversities of equipment. This, of course, prevents the use of the same vessel for through transportation, and so transhipments are required, which increase considerably the cost of conveyance. Again, it is almost always necessary to transfer from vessels to rail and *vice-versâ*, since most freight consignments are either destined to points away from waterways or else originate at such points.

The following quotation is from the Report of the Commissioner of Corporations on Transportation by Water in the United States under date of July, 1909 :

It cannot be expected that any reasonable expenditure on our inland waterways will wholly remove these difficulties.

Transportation by water in the United States cannot be brought to the same degree of uniformity as on railroads, with a few standard types of vessels available for all classes of waterways. Water-borne traffic will continue to be carried, for the most part, in vessels adapted to particular classes of waterways and the special traffic of such waterways.

Through traffic moving from one waterway to another will require transshipment. Even on long inland hauls, transshipment will often be necessary. Moreover, traffic to and from many points not on a waterway must continue to be carried, at least for part of the distance, by rail, and transshipment will be necessary if such traffic is to move even in part by water.

Slow movement of traffic.

In many cases, the time required for transit by inland navigation lines is so great as to render competition with railroads out of the question. In the State of New York, for example, the time for through service by waterways is from ten to fifteen times as long as that taken by rail carriers.

More than this, the service by water is irregular and uncertain.

Canal breaks are of frequent occurence, and, on account of these, traffic is tied up for weeks at a time.

Waterway terminals.

Another element of disadvantage to waterway transportation in comparison to conveyance by rail is found in the difficulty of obtaining suitable terminals on account of extreme changes in water level which continually occur in times of freshets and droughts.

Marine insurance.

An important factor in the cost of water carriage is the insurance rate.

Railroad companies are compelled to assume the risk of loss of goods in transit as a part of operating expenses. Water carriers on the contrary, for the most part, are obliged to take out insurance on such property, and this must be added to the freight rate. Shippers therefore find it necessary to consider this item in order to determine the relative economy of water routes in comparison with rates by rail. In some cases however the shipper himself insures his goods in transit, and, again we find, in rare instances, no insurance whatever is carried.

On the Mississippi River, from Vicksburg to New Orleans, the freight rate on cotton is seventy five cents per bale, while cargo insurance is about twenty cents per bale in addition, making the insurance almost a third of the cost of the freight charge.

On the Red River, cargo insurance is 0·9 per cent of the value of the goods carried, while on Virginia and Maryland waterways, the insurance premium amounts to 3·1 per cent of the gross receipts of transportation companies.

It will be seen at once that these high rates, varying greatly also in different localities, operate strongly to the disadvantage of water carriers.

Government supervision.

A systematic, rigid inspection of vessels by the Government, and the strict requirements thereby imposed as to construction, operation and maintenance, are generally considered to affect water transportation unfavorably in comparison with railroads, although it is apparent that government control of railroads in the United States is steadily increasing in extent every year.

Taking into account then all the existing elements of disadvantage which have been referred to in connection with waterways, it is not surprising that they have so little effect in the way of competition with railways, and that they act for the most part, merely as feeders to railway lines.

Efforts have been made from time to time to make waterways an active part in our transportation system by means of government aid, and, at every session of our national congress, appropriations are passed for river and harbor improvements, generally on a liberal scale.

The total appropriations for inland river improvements alone, up to 1907, have been over 250 million dollars.

Government commissions have been appointed also to investigate the subject of waterway improvement and construction. In consequence of this, there is, at present in the United States, as in Europe, considerable popular agitation on the subject.

It is apparent however that if any efficient development is to be undertaken, it will be necessary to devise a comprehensive plan which must involve enormous expense, and it is altogether doubtful if the results would, by any means, justify the cost of such an enterprise.

At the present time, the State of New York is enlarging the Erie Canal to a twelve foot depth at an estimated cost of over 100 million dollars. A recent decision of the courts however as to liability for damages caused by this canal construction will bring the final cost far above this figure.

Up to the year 1909, the cost of the old Erie Canal, 352 miles long, has been approximately 57,600,000 dollars for a waterway which carries less than 3 per cent of the tonnage now taken by competing railways.

On the completion of the work of enlargement, there will be an additional burden of probably at least 125 million dollars expenditure imposed on the people of the state, notwithstanding the fact that grain rates on parallel railroad lines are less than four mills per ton-mile.

At 4 $^1/_2$ per cent, the interest on this total cost of construction amounts to 8,217,000 dollars yearly, to say nothing of the cost of maintenance and operation. For the ten years previous to 1908, there was an average movement of only 2 242,648 tons per annum on the entire canal. Official reports do not give the length of haul, but if a most liberal assumption in this regard is made in the same ratio to tonnage as on the railroads and canalized rivers adjacent, it will be seen at once what a disproportionalety heavy charge must be added to the actual cost of carriage based on operation and maintenance in order to make the canal self sustaining.

[385 .2]

REPORT N° 2

(all countries except Great Britain and America)

By C. COLSON,

GENERAL INSPECTOR OF BRIDGES AND ROADS,
STATE CONCILLOR OF FRANCE,

and Louis MARLIO,

ENGINEER OF BRIDGES AND ROADS

Purpose and plan of the report.

We do not think that the Congress, in placing on its agenda " the investigation of the influence of waterways considered as feeders and as competitors, on railways ", has had the intention of reopening, from a theoretical and speculative point of view, the question, so frequently discussed, of the competition between railways and waterways. It seemed to us that the interest of this work was to show, by a direct investigation of the facts, what the results of the competition or the co-operation of the two systems of carriage are in actual practice, and what the factors are which influence the division of the traffic between them.

Our enquiry was to extend to all countries, except the British Isles and the United States of America. We have sent lists of questions to all the railway administrations which, as far as we know, could have important relations with waterways.

We have received a large number of interesting answers. We must particularly mention the remarkable and extensive work supplied by the French Eastern Railway,

then also the answers sent by the French Northern, the French Western and the Orleans railways in France; by the Alsace-Lorraine State Railway, the Bavarian State Railway, the Baden State Railway, the Austrian State Railway and the Hungarian State Railway, In one case only were no answers supplied, namely by the administration of the Prussian State Railway which stated that it " regretted to have to refuse to answer question XIII "; we have done our best to supplement missing information.

It is after considering the answers received, the supplementary information which has been supplied to us by the administrations of railways and that which we were able to collect directly, that we are going to try to present a report on the question. The most important part of this report will consist in a review of the different factors which influence the distribution of the traffic between the two forms of conveyance, the chief being : the rates for carriage, the amount of the accessory charges, the length of the journey and the time it takes, the nature and value of the goods, the class and the habits of the customers, the situation of the places of origin and of destination, the direction of the traffic, whether import or export. All of these factors tend to produce a normal state of equilibrium which other influences may modify, for instance, the temporary influence of variations in the industrial activity.

According to the situation resulting from these different factors, the railway administrations are led to look upon waterways as allies at one time and as adversaries at another, and the difference in their opinions on this point in its turn reacts on the traffic conditions.

But in order clearly to understand the facts observed in the different countries, it is essential in the first place to know the administrative and financial regime of the railways and the waterways in each of them, and in the second, to know what are the essential characters of these latter from the technical and economic point of view. We will accordingly make a short examination of them, taking the chief countries, Russia, Germany, Austria, Hungary, France, Belgium, Holland, in succession. We shall add some statistical information which will make it possible to grasp the very varying importance, according to locality, of traffic by water as compared with traffic by rail.

This preliminary geographical review will enable us to deal more rapidly with the methodical consideration of the other aspects of the question. We will then examine the function of the different factors mentioned above, and make a comparative investigation regarding the net cost of carriage, by the two systems of conveyance, of traffic carried under conditions as nearly similar as possible.

FIRST PART.

Situation of the railways and waterways in the different States.

RUSSIA.

I. — Extent. — Geographical situation. — Cost of construction.

A. — *Railways.*

In 1905 the railways of Russia in Europe had a total length of 49,000 kilometres (30,450 miles), and had cost 9·5 milliards of francs (£380 millions), or 193,000 francs per kilometre (£12,424 per mile). This very low figure is due to the low price of land, to the flat nature of the greater part of the territory and to the large use of level crossings where roads are crossed. In spite of its extent, the Russian railway system is still a very large mesh one, owing to the vast size of the country; it has however hence been wisely avoided to locate railways near great rivers, which offer navigation sufficient facilities for coping with the traffic, such as the Volga and the lower Dnieper.

B. — *Waterways.*

The international navigation of Russia presents very special characters.

It is much favoured by the very gentle fall of the rivers. The central mass of Russia, which forms its culminating point, is in fact only 300 metres (984 feet) above sea-level.

The navigation is on the other hand impeded :

1° By insufficient connexion with sea navigation, as it ends in closed seas ;

2° By a very long duration of the period of frost, which makes it impossible to utilize the rivers during five months of the year.

There are few connections between the different basins. However, in order to save the traffic passing from one to the other, the expense of cartage over long distances, or even of porter's work (which has not entirely disappeared yet), there were built, before the development of the railways, navigable " systems " utilizing the tributaries of rivers or lakes, and connecting them by means of canals.

Two systems were begun between the Don and the Volga and remained uncompleted. There are two (the Catherine and the Duke of Wurtemberg systems) between the Volga and the White Sea; the first is abandoned. Finally, the Volga and the Neva are connected by the Vychnyolotschock and the Marie systems; the latter alone is of importance as it takes the traffic between the Volga and St. Petersburg.

The length of the waterways in Russia in Europe (Finland excluded) is 57,000 kilometres (35,420 miles), of which hardly 2,000 kilometres (1,242 miles) are artificial waterways.

The principle Russian river is the Volga, 3,300 kilometres (2,050 miles) of which are navigable, not counting its two chief tributaries the Oka and the Kama, which have 1,300 and 1,200 kilometres (807 and 745 miles) navigable respectively. The chief traffic on the Volga is on the 2,650 kilometres (1,646 miles) between Rybinsk and Astrakhan. The fall of the river varies on the different sections between 2 and 6 centimetres per kilometre (1·27 and 3·81 inches per mile). Its flow at low water increases from 300 to 3,300 cubic metres (10,600 to 116,500 cubic feet) per second, as we descend the river.

The depth of the channel at low water is 1·24 metres (4 ft. 1 in.) from Rybinsk to Nijni and 1·60 metres (5 ft. 3 in.) below Nijni; the current then only has a velocity of 25 to 70 centimetres (10 inches to 2 ft. 3 $^{9}/_{16}$ in.) per second. At high water (April-June) the current is stronger and sometimes even is as fast as 2 metres (6 ft. 6 $^{3}/_{4}$ in.) per second. But the river is then accessible for boats drawing 3 to 4 metres (10 to 13 feet) of water.

II. — Administrative regime.

A. — *Railways.*

At first there were companies with interest guaranteed, but now the chief system is that of operation by the State; in 1905 there were 31,000 kilometres (19,260 miles) operated by the State, as against 18,000 kilometres (11,185 miles) still operated by companies.

Before the Russo-Japanese war and the subsequent crisis, the operation of the Russian railways resulted in a profit representing 4 or 5 per cent on capital. The gross receipts amounted in 1905 to 1,744 million francs (£69,760,000), or 32,900 francs per kilometre (£2,118 per mile).

The rates of the private companies are subjected to strict control.

The State levies a tax of 15 per cent on the tickets of passengers exceeding 2 copecks (0·58*d.*), on luggage and on parcels; this brings in about 45 million francs (£1,800,000).

B. — *Waterways.*

All the Russian waterways are built, improved and maintained by the State.

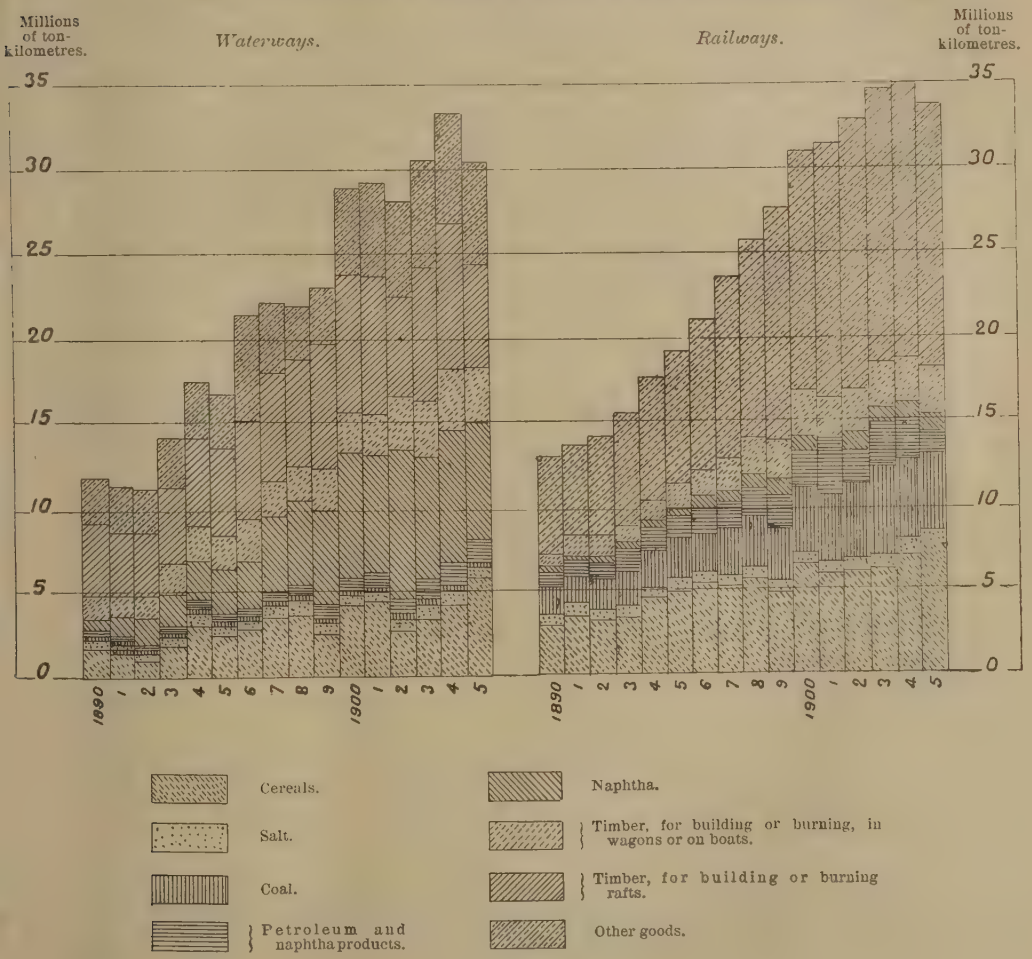
The annual expenditure incurred by the State for the purpose amounted in 1907 to 38 million francs (£1,520,000).

Ten years ago, the tolls which existed on the rivers and which brought in 2 or 3 million francs (£80,000 or £120,000) per year were abolished. A toll of $^{1}/_{2}$ per cent of the declared value of the cargo is still charged on the Ladoga canals, which form part of the Marie system. The amount yielded by these tolls is very small.

III. — Particulars of the traffic.

The diagram given below (fig. 1) represents, in millions of ton-kilometres, the amount of traffic carried on the railways and on the waterways of Russia in Europe as well as the composition of each kind of traffic classified under its principal headings.

Fig. 1. — **Goods traffic in Russia in Europe in the years 1890-1905.**



Very nearly the same amount of traffic is carried by the two different means of conveyance. This equality has been maintaining itself for twenty years, although there are marked fluctuations in the waterways traffic. These fluctuations are due to annual variations in the climatic conditions, which have a direct influence on the river navigation.

The progress of the traffic in the principal goods, in millions of ton-kilometres (in millions of English ton-miles), in the years 1885-1905, is shown in the table below.

ARTICLE.	Railways			Waterways		
	in 1885.	in 1905.	Increase per cent.	in 1885.	in 1905.	Increase per cent.
Cereals	2·97 (1·82)	7·88 (4·82)	165	1·92 (1·17)	6·30 (3·85)	228
Salt	0·70 (0·43)	0·70 (0·43)	...	0·44 (0·27)	0·53 (0·32)	20
Petroleum and naphtha.	0·61 (0·37)	2·10 (1·28)	244	0·53 (0·32)	8·75 (5·35)	1,551
Timber	0·70 (0·43)	2·62 (1·60)	274	4·29 (2.62)	10·15 (6·21)	137
Coal	1·14 (0 70)	4·72 (2·89)	314	0·09 (0·06)	0·17 (0·10)	89
Miscellaneous goods.	4·03 (2·46)	16·10 (9·85)	300	2·27 (1·39)	6·48 (3·96)	185
Total.	10·15 (6·21)	34·12 (20 87)	236	9·54 (5·83)	32·38 (19·79)	239

We may note the great increase in the naphtha traffic on waterways and the increase in the miscellaneous goods (manufactured articles and articles of value) traffic on railways.

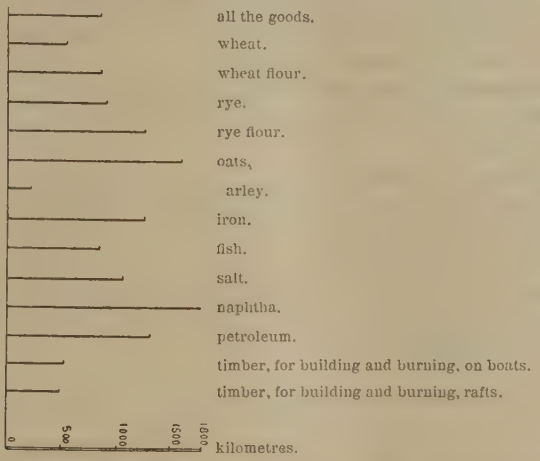
When, instead of dealing with the ton-kilometres, we compare the number of tons, we get the following figures :

	Railways.	*Waterways.*
In 1885	24,764,000 tons.	13,480,000 tons.
In 1895	42,771,000 —	23,878,000 —
In 1905	67,272,000 —	34,987,000 —

Although the tonnage has become more than doubled on railways, the mean distance the goods are carried is half less. It is estimated at 475 kilometres (295 miles), whereas on waterways it reaches the enormous figure of 950 kilometres

(590 miles). The adjoining diagram (fig. 2) shows the mean distance the chief classes of goods are carried on the waterways; from barley, which is only carried 200 kilometres (124 miles), to naphtha, which almost reaches 1,800 kilometres (1,120 miles).

Fig. 2. — **Mean distance goods are carried.**



The traffic on the Volga amounts to 16 million tons, or nearly half the total traffic on the Russian waterways; and with tributaries, to 20 million tons, or four sevenths of the total. The Volga traffic, which has tripled from 1885-1905, consists of one quarter of naphtha, one quarter of timber and one quarter of cereals. The main direction of the traffic is up river. Next to the Volga, the Dnieper must be mentioned, which has a traffic of more than 4 million tons, three fifths of which consist of timber carried either on boats, or more usually in the form of rafts. Finally the Marie system receives 2 million tons, 1·7 of which go to the Neva.

The following table shows the traffic at the most important ports in 1905:

Astrakhan	6.3	million tons.		Tsaritsyne.	1·5	million tons.	
St. Petersburg . . .	5·6	—	—	Saratov	1·5	—	—
Nijni-Novgorod . . .	2·7	—	—	Samara	1·5	—	—
Rybinsk	1 7	—	—				

These are all on the Volga, except St. Petersburg which is on the Neva.

IV. — Particulars of the rates.

The rates of the Russian railways are very low, particularly for long distances. The mean rate of 3·10 centimes per ton-kilometre (0·49*d.* per ton-mile) charged in 1905 is the lowest in the whole of Europe, in spite of the small importance of the

coal and mineral traffic, which represent generally the chief goods paying the lowest rates.

The freight charged on the Russian waterways varies extremely, according to their navigability.

The most favoured river is the Volga. It has a fleet of 1,700 steamships, 400 of which carry passengers; the others are used principally for naphtha. The boats attain large sizes and can carry up to 4,000 tons; we have even seen a naphtha boat of recent construction having a *capacity of 9,000 tons*. The greater part of the traffic is carried in barges carrying from 1,000 to 3,000 tons, hauled in lots which may reach 16,000 tons and which take thirty-three to thirty-six days to go up the Volga from Astrakhan to Rybinsk.

Freight is lower in spring than in autumn. It varies with the nature of the goods and may be estimated, on the average (1901-1905) at 0·4 centime the ton-kilometre (0·06*d*. per English ton-mile) in the case of naphtha, 0·5 centime (0·08*d*) in that of cereals and salt, and 0·7 centime (0·11*d*.) in that of iron.

The difference in the cost of carriage on the different Russian waterways may be estimated from the following table, which gives the mean freight charged on the chief ones for cereals in 1905 :

Volga	0·5 centime	per ton-kilometre	(0·08*d*.	per English ton-mile).
Duna	0·9	—	—	(0·14*d*.	—	—).
Marie system . . .	1·2 centimes	—	(0·19*d*.	—	—).
Dnieper	1·8	—	—	(0·28*d*.	—	—).
Don	2·7	—	—	(0·42*d*.	—	—).

V. — Mixed traffic.

Mixed traffic is particularly important in Russia. It has grown rapidly of late, as shown in the table below. The table on the following page shows, for 1905, the tonnage and nature of the chief goods transhipped from wagon to ship or vice versa, at the most important tranship ports.

—	1890.	1905.	Increase, per cent.
Number of tons transhipped from wagon to ship .	0·5 million.	1·4 million.	180
Number of tons transhipped from ship to wagon. .	2 millions.	4·5 millions.	125
Total. . .	2·5 millions.	5·9 millions.	170

A = Transhipment from wagon to ship (in thousands of tons).
B = — — ship to wagon (— —).

PORT.	Cereals.		Salt.		Naphtha.		Petroleum.		Coal.		Wood for burning.		Timber for building.		Transhipment from		*Total.* (A and B)
															railway to waterway	waterway to railway.

Kalatsch (Don)	37	8	3	...	...	...	9	...	...	...	...	...	113	...	162	8	170
Riazan (Oka)	1	1	...	1	...	101	...	...	...	...	...	16	...	32	1	151	152
Pokrovskaia (Volga)	134	3	...	...	...	...	...	...	...	...	...	6	...	13	134	22	156
Nijnedneprovsk (Dnieper)	...	...	55	...	...	...	...	...	18	...	...	4	1	65	74	69	143
Other ports	277	135	8	24	...	55	...	48	18	3	16	38	57	473	376	776	1,152
Total.	862	740	433	159	...	1,866	9	488	72	3	19	72	185	1,051	1,580	4,379	5,9

The total figure for 1905 represents 9 per cent of the total railway traffic. It is to be noted that it is really greater, for the data only apply to seven classes of goods, two of which (coal and wood for burning) only represent an insignificant tonnage.

Transhipments from wagon to ship are only important in the case of cereals (on the Dnieper and at certain Volga ports) and of salt, which the port of Wladimirovka (Volga) receives from Russia in Asia by a railway of which it forms the terminus.

Transhipments from ship to wagon are much more important; they include chiefly naphtha (nearly 2 million tons) transhipped at the middle and upper Volga ports (Jaroslav, Nijni, Saratov, Kinechma), for conveyance to Moscow and St. Petersburg, and building timber (1 million tons) transhipped at the ports of the lower Volga and Dnieper.

GERMANY.

I. — Extent. — Geographical situation. — Cost of construction.

A. — *Railways.*

At the end of 1907, the total length in operation was 56,000 kilometres (34,800 miles), which had cost 19·5 milliard francs (£780 millions), or about 350,000 francs per kilometre (£22,530 per mile). There are also nearly 10,000 kilometres (6,214 miles) of narrow-gauge lines, some of general interest, others purely local.

B. — *Waterways.*

The total length of the German waterways is 13,000 kilometres (8,078 miles), including 2,400 kilometres (1,491 miles) of canalized rivers and 2,400 kilometres (1,491 miles) of canals. The length really frequented by vessels does not exceed 10,000 kilometres (6,214 miles). Half of the system is accessible to boats drawing more than 1·50 metres (4 ft. 11 in.) of water.

It will be seen further on that four fifths of the traffic are concentrated on 1,800 kilometres (1,118 miles) on the rivers : the Rhine, the Elbe and the Oder. These three rivers have a very slight fall : the height of 100 metres (328 feet) is attained at distances from the sea of 621, 662 and 524 kilometres (386, 411 and 325 miles) respectively. As a rule, steam tugs are used. On the Elbe and the Oder the boats generally have a tonnage of 400 to 600 tons. On the Rhine, the usual figure is 1,000 tons; exceptionally it amounts to 2,000 or even 2,800 tons. The depth of water under ordinary low-water conditions in the case of the latter river is 3 metres (10 feet) up to Cologne, 2·50 metres (8 ft. 2 in.) up to St. Goar,

and 2 metres (6 ft. 6 3/4 in.) up to Mannheim. The Rhine and the Elbe do not wind much and consequently the boats do not go much round.

Navigation on the German rivers is suspended by the ice during a period which varies from one to three months according to season and to district. This unfavourable influence is particularly marked in eastern Prussia. On the other hand low water in summer frequently compels the boats to run without a full load.

The Rhine and the Elbe are free-running rivers. The same applies to the Oder, except as regards the upper section, 80 kilometres (50 miles) of which are canalized.

The most important canals in Germany are those belonging to the old Brandeburg system, which has Berlin as its centre, and the new Dortmund-Ems canal. These are accessible to boats of 400 and 600 tons.

The amount spent from 1816 to 1905 on inland navigation by the Prussian State, whose territory contains nearly all the German waterways, may be classified as follows :

Rhine, Weser, Elbe, Oder	180 million francs	(£7,200,000).
Canals and canalized rivers.	230 —	— (£9,200,000).

We do not include in this the important expenditure incurred, chiefly in the interests of agriculture, on the waterways of eastern Prussia, and on the canal from the North Sea to the Baltic, built for naval purposes.

Nor do these figures include the expenditure of the different districts on inland ports, which exceeds 200 million francs (£8,000,000). In this total the port of Berlin, which has but primitive installations, only figures with 2·5 million francs (£100,000).

II. — Administrative regime.

A. — *Railways.*

At the beginning of 1907, the German States themselves operated 52,000 kilometres (32,312 miles) out of the existing total of 56,000 kilometres (34,800 miles) of railways.

The operation of these railways is a considerable source of revenue to the State budgets. The net profit, calculated after deducting the sums, not included in the railway budgets, paid towards pensions, represented in 1907, as compared with the capital cost, more than 6 per cent in Prussia, 5 per cent in Saxony, nearly 4 per cent in Bavaria, and only 2·5 per cent in Wurtemberg.

The whole of the German standard-gauge lines showed in 1907 gross receipts of 3,428 million francs (£137,120,000) and expenses (pensions included) of 2,382 million francs (£95,280,000), or a net profit of 1,046 millions (£41,840,000), representing 5·35 per cent on the capital outlay.

No special tax was charged on railway traffic until recently. In 1906, a tax was

instituted, on behalf of the Empire, in the form of a stamp, on passenger tickets and way-bills; this yields 40 million francs (£1,600,000), obtained chiefly from passengers.

B. — *Waterways.*

The maintenance of the waterways costs the State each year about 20 million francs (£800,000).

Germany has long admitted that the State should see to the improvement and the maintenance of the natural waterways and that their use should be free. This freeness is guaranteed, in the case of all rivers, by the imperial constitution, and as regards the two chief, by international agreements as well.

Tolls have on the other hand been instituted, and then gradually raised, on the canals and the canalized rivers. These tolls always include several classes, so as to take into account the value of the goods. The tariffs differ on the different waterways. The following are the chief :

			Per ton-kilometre.	(Per English ton-mile.)
Dortmund-Ems canal	4 classes	0·4 to 0·06	centime	(0·06*d.* to 0·09*d.*)
Brandenburg waterways	4	— 0·2 to 0·5	—	(0·03*d.* to 0·08*d.*)
Canalized Main	2	— 0·4 to 0·8	—	(0·06*d.* to 0·13*d.*)
— Oder	4	— 0·2 to 0·8	—	(0·03*d.* to 0·13*d.*)
— Weser	3	— 0·3 to 0·9	—	(0·05*d.* to 0·15*d.*)

Except in the case of the Brandenburg waterways, these tolls do not even cover the cost of maintenance. The following is the financial situation of the waterways as regards the State :

—	Annual receipts 1905.	Annual cost of administration and maintenance. 1905.	In order to cover the annual expenses plus 3·5 per cent on the capital for interest and amortization, the receipts would require the following increase.
	Francs.	Francs.	Francs.
Free-running rivers	1,250,000 (£50,000)	13,265,000 (£530,600)	23,936,000 (£957,440)
Canals and canalized rivers	7,272,000 (£290,880)	6,856,000 (£274,240)	10,410,000 (£416,400)
Ports belonging to the State	5,760,000 (£230,470)	6,182,000 (£247,280)	7,176,000 (£287,040)
Total	14,282,000 (£571,280)	26,303,000 (£1,052,120)	41,522,000 (£1,660,880)

As regards the inland ports, both communal and private, the annual receipts (9,543,000 francs [£381,720]) cover the annual cost of administration and mainte-

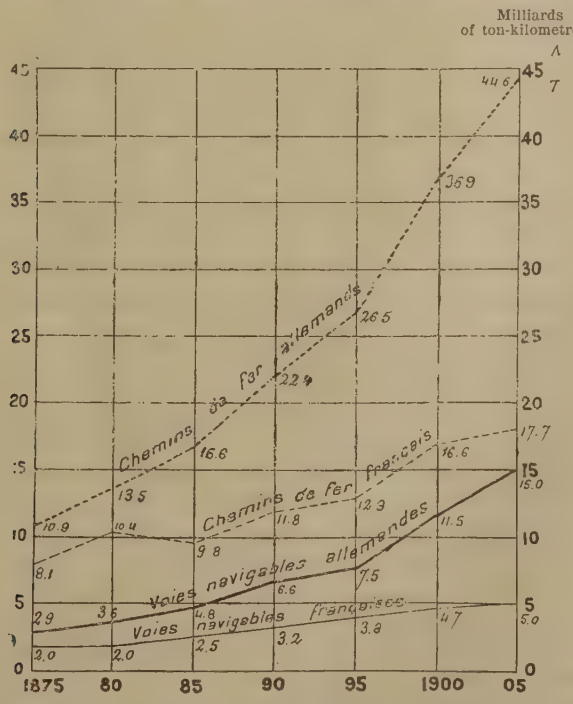
nance (6,800,000 francs [£272,000]) and give a net profit representing about 2·5 per cent on the capital outlay.

In a recent bill providing for large extensions and improvements in the inland waterways, the Prussian parliament introduced a clause to enable tolls to be levied on free-running rivers, in order to cover the cost of maintenance and that of new works intended to facilitate navigation. This clause being invalid under the imperial constitution, the imperial government brought forward, on 13 March 1909, a proposal to amend the constitution on this point.

III. — Particulars of the traffic.

The diagram given below (fig. 3), taken from the work published every five years by Mr. Sympher, compares the progress of the traffic on railways and on waterways, in France and in Germany, from 1875 to 1905 :

Fig. 3. — **Goods traffic on railways and waterways.**



Explanation of French terms : Chemins de fer allemands = German Railways. — Chemins de fer français = French railways. — Voies navigables allemandes = German waterways. Voies navigables françaises = French waterways.

The proportion of the inland waterway traffic, as compared with the total traffic, nas increased from 21 to 25 per cent in Germany during this period.

The mean distance slow-freight goods are carried on railways dropped from 164 to 114 kilometres (102 to 71 miles) during the period 1885-1905. On the waterways, on the other hand, it increased from 280 to 290 kilometres (174 to 180 miles)(1) during the period 1875-1905. We show in the table below how according to Mr. Sympher the traffic on the German waterways is distributed.

BASINS.	Length in kilometres (in miles).	Number of ton-kilometres (English ton-miles) per year.	Mean traffic per kilometre (per mile) per year, in tons.
Rhine	2,480 (1,541)	6,986,000,000 (4,270,000,000)	2,817,000
Elbe	1,093 (699)	3,649,000,000 (2,232,000,000)	3,339,000
Oder	1,327 (825)	1,660,000,000 (1,015,000,000)	1,251,000
Brandenburg canals	1,243 (772)	1,590,000,000 (972,000,000)	1,279,000
Ems	332 (206)	239,000,000 (146,000,000)	720,000
Vistula	353 (219)	204,000,000 (125,000,000)	578,000
Weser	644 (400)	184,000,000 (113,000,000)	286,000
Miscellaneous	1,978 (1,229)	298,000,000 (182,000,000)	151,000
Total and mean	9,450 (5,872)	14,810,000,000 (9,057,000,000)	1,567,000

The corresponding figures for the three chief rivers (without their tributaries) are:

BASINS.	Length in kilometres (in miles).	Number of ton kilometres (English ton-miles) per year.	Mean traffic per kilometre (per mile) per year, in tons.
Rhine (from Kehl to the Dutch frontier)	570 (354)	6,493,000,000 (3,971,000,000)	11,400,000
Elbe (from the Austrian frontier to Hamburg)	621 (386)	3,584,000,000 (2,192,000,000)	5,770,000
Oder (from Kosel to Stettin)	641 (398)	1,433,000,000 (876,000,000)	2,240,000
Total and mean	1,832 (1,138)	11,510,000,000 (7,039,000,000)	6,290,000

(1) According to Mr. Sympher, and taking into consideration the foreign mileage of goods imported or exported.

If we leave out of consideration in the case of the Rhine the 130-kilometre (81-mile) section between Mannheim and Kehl, where the traffic at each point decreases as we ascend, from 3 to 1 million tons, we find on the 440 kilometres (273 miles) included between the Dutch frontier (Emmerich) and Mannheim, four ninths of the total traffic of the German waterways; the mean traffic per kilometre per year exceeds 15 million tons.

The traffic of the chief ports in 1905, in thousands of tons, is given in the table below.

CHIEF PORTS.		Number of tons		TOTAL.
		received.	dispatched.	
Rhine basin	Duisburg group	7,930	11,532	19,462
	Mannheim	4,309	987	5,296
	Ludwigshafen	1,306	515	1,821
	Frankfort on the Main	1,311	269	1,580
Elbe basin	Hamburg	3,113	4,740	7,853
	Magdeburg	1,301	767	2,008
Oder basin	Stettin	793	1,678	2,471
	Kosel	181	1,382	1,513
Brandenburg waterways	Berlin-Charlottenburg	9,414	700	10,114

IV. — Particulars of the rates.

A. — *Railway.*

The general and special tariffs include the station charges, to which the charge for loading and unloading have to be added in the case of goods not sent in full truck-loads, of which there however but few. The rate charged is in principle proportionate to the distance. The initial rates, expressed in centimes per ton and per kilometre (in pence per English ton and per mile), are as follows for truck-loads of 5 tons (tariffs A 1, and A 2) or of 10 tons (tariffs B, I, II, and III), slow freight :

General tariff.		Special tariff for certain goods.			
A_1	B	A_2	I	II	III
8·375	7·5	6·25	5·625	4·375	3·25
(1·315)	(1·177)	(0·981)	(0·883)	(0·687)	(0·510)

The initial rate of special tariff III becomes reduced to 2·75 (0·432*d.*) beyond

100 kilometres (62 miles); the others do not decrease when the distance increases.

More important are the exceptional tariffs which apply to two thirds of the slow-freight traffic of Germany. These tariffs often have fixed initial rates; the rate per kilometre however decreases in some cases at great distances. The most reduced tariffs are the *sea-port tariffs*, which are intended to favour German export trade, or else the import of goods which Germany does not produce.

B. — *Waterways.*

Freight is very variable according to the technical, geographical and economical value of the different waterways. It varies on each river with the time and the nature of the goods; the variation can attain 50 per cent in the first case and 20 per cent in the second. Here are some instances of the average freight charged on the chief articles carried :

WATERWAYS.	Article.	Journey.	Distance in kilometres.	Freight		*Remarks.*
				total in francs.	per ton-kilometre, in centimes (per English ton-mile, in pence).	
Rhine	Cereals	Rotterdam-Mannheim.	543 (337)	3·80 (3*s.* 1·1*d.*)	0·66 (0·104)	Average 1901-1905.
	Coal	Duisburg-Mannheim.	326 (203)	3·25 (2*s.* 7·7*d.*)	0·92 (0·144)	Freight artificially increased by 20 to 30 per cent since the formation of the Kohlen-Kontor.
	Coal	Duisburg-Rotterdam.	217 (135)	1·30 (1*s.* 0.7*d.*)	0·60 (0·94)	Average 1896-1905.
	Half manufactured	Ludwigshafen-Rotterdam.	550 (342)	2·00 (1*s.* 7·5*d.*)	0·35 (0·055)	Return freight.
Dortmund - Ems canal	Coal	Dortmund to Emden.	270 (168)	2·06 (1*s.* 8·1*d.*)	0·75 (0·118)	Not counting tolls.
Weser	Cereals	Bremen-Hameln.	244 (152)	5·37 (4*s.* 4·4*d.*)	2·25 (0·353)	
	Sugar	Hameln-Bremen.	244 (152)	2·18 (1*s.* 9·3*d.*)	0·90 (0·141)	Return freight.
Elbe	Coal	Aussig-Magdeburg.	366 (227)	3·30 (2*s.* 8·2*d.*)	0·9 (0·141)	The freight on the Elbe has since 1904 a tendency to go up, in consequence of a combine between the chief shipping companies.
	Cereals	Hamburg-Dresden.	581 (361)	6·91 (5*s.* 7·4*d.*)	1·21 (0·190)	
Oder	Coal	Breslau-Berlin.	567 (352)	6·92 (5*s.* 7·5*d.*)	1·22 (0·192)	Average 1897-1906.

If we consider, not the total value, but the variation in the freight, we find that during the last thirty years, this has fallen on the average : 40 to 60 per cent on the Rhine, 30 to 50 per cent on the Weser and 30 per cent on the Brandendurg canals.

During the same period the rates on the Prussian railways have on the average been reduced by 16 per cent and on the whole of the German railways by 19 per cent.

V. — Mixed traffic.

We give particulars below of the tonnage transhipped at the chief German ports from wagon to boat and from boat to wagon. The figures refer to 1905, unless otherwise stated.

WATERWAYS.	PORT.	Number of tons transhipped		Total per port.
		from wagon to boat.	from boat to wagon.	
Rhine	Lauterburg	...	375,000	375,000
	Karlsruhe	90,000	405,000	495,000
	Strasburg	227,000	470,000	697,000
	Mannheim	370,000	2,053,000	2,423,000
	Rheinau	...	1,270,000	1,270,000
	Frankfort	212,000	461,000	673,000
	Gustavsburg	15,000	853,000	868,000
	Cologne (1908)	164,000	266,000	430,000
	Duisburg-Ruhrort-Hochfeld	10,283,000	3,905,000	14,188,000
	Others ports	62,000	538,000	600,000
	Totals.	11,423,000	10,596,000	22,019,000
Elbe	Dresden (1906)	115,000	285,000	400,000
	Riesa (1906)	47,000	484,000	531,000
	Schönebeck	445,000	78,000	523,000
	Magdeburg	458,000	661,000	1,119,000
	Harburg	153,000	251,000	404,000
	Other ports	137,000	333,000	470,000
	Totals.	1,355,000	2,092,000	3,447,000
Weser	Cassel, Hameln, Minden	173,000	112,000	285,000
Dortmund-Ems Canal	Munster, Dortmund, etc.	93,000	281,000	374,000
Oder	Kosel	1,388,000	176,000	1,564,000
	Breslau	629,000	143,000	772,000
	Other ports	110,000	38,000	148,000
	Totals.	2,127,000	357,000	2,484,000
Danube	Passau-Ratisbon	53,000	243,000	296,000

*

We can summarize these results in the following table :

WATERWAYS.	Number of tons transhipped		Total.
	from wagon to boat.	from boat to wagon.	
Rhine	11,423,000	10,596,000	22,019,000
Elbe	1,355,000	2,092,000	3,447,000
Weser	173,000	112,000	285,000
Dortmund-Ems Canal	93,000	281,000	374,000
Oder	2,127,000	357,000	2,484,000
Danube	53,000	243,000	296,000
General total. . .	15,224,000	13,681,000	28,905,000

The particulars we have just given are necessarily incomplete. We were unable to obtain the figures of some ports, particularly of the two great ports of Düsseldorf and Ludwigshafen.

Hence it does not seem doubtful that the tonnage of the transhipments exceeds thirty million tons. This figure does not however correspond to the actual tonnage of the mixed traffic, as certain goods were transhipped twice. This is the case with coal from Westphalia, first shipped at one of the Ruhrort ports and transhipped a second time at Gustavsburg, Frankfort, Mannheim, Rheinau, Ludwigshafen, Strasburg, Lauterburg and Karlsruhe. The tonnage of these goods which are twice transhipped may be estimated at 4·5 or 5 million tons.

Taking it altogether, of the 66 millions tons carried on German waterways, 4·5 to 5 millions tons have used a railway twice, and about 21 millions tons have used it once only.

In these transhipment figures, the chief part is taken by the Rhine (more than 22 million tons), and on that river, by the group of Ruhrort port (14 million tons). The latter traffic consists, as far as arrivals are concerned, of ore and cereals going to Westphalia, and, as far as departures are concerned, of Ruhr coal (9,500,000 tons) going to Holland (2,500,000 tons), to Belgium (1 million tons) and to ports on the Upper Rhine and their Hinterland (6 million tons).

The tonnage transhipped represents about 7 per cent of the total 400 million tons carried on the railways in 1905.

AUSTRIA.

A. — *Railways.*

The total length of railways in operation in 1906 in Austria amounted to 18,800 kilometres (11,680 miles), which had cost 5,800 million francs (£232 millions) (a little less than half of this had been spent by companies), or about 360,000 francs per kilometre (£23,174 per mile).

At that time, the State operated 13,000 kilometres (8,078 miles). But the State since then has taken over several companies, namely the Kaiser Ferdinands Nordbahn (1907), the Bohemian Northern Railway (1908), the Austro-Hungarian State Railway Company and the Austrian North Western Railway (1909). Except the Austrian Southern Railway, there are still in existence only companies of very little importance.

The goods traffic on the whole system amounted to 10,200 million ton-kilometres (6,238 millions English ton-miles).

The total receipts amounted to nearly 700 million francs (£28 millions), the expenses to 440 millions (£17,600), and the net profit to nearly 260 millions (£10,400,000), representing 4·4 per cent on the capital outlay.

The tariffs contain the same conditions and are of the same type as those of the German railways. Those of the companies are uniformized. Special agreements are authorized, provided that any resulting advantages are granted to every consignor accepting the conditions.

The Austrian State levies a tax of 12 per cent on the passenger fares, which yielded 17·5 million francs (£700,000) in 1905.

In addition there are 2,665 kilometres (1,656 miles) of railways of Austria and Hungary jointly, the chief item being the Austrian Southern Railway. This system has cost 1,400 million francs (£56 millions) and has a total length of 2,200 kilometres (1,367 miles), of which 1,530 kilometres (950 miles) are on Austrian territory. Its goods traffic amounted in 1906 to 2,280 million ton-kilometres (1,394 million English ton-miles). The net profit amounted to 60 million francs (£2,400,000), representing 4·2 per cent on the capital outlay.

B. — *Waterways.*

In Austria there are 2,600 kilometres (1,616 miles) of waterways, all rivers; 1,300 kilometres (808 miles) of them can take steamships.

The only important waterways are the Danube, 365 kilometres (227 miles) the Elbe, 109 kilometres (68 miles), and its tributary the Moldau, 242 kilometres (150 miles).

The Upper Danube is but a poor waterway; it has a current of 1·80 metres (5 ft. 11 in. per second, all the more objectionable as the bulk of the traffic is up river. The Moldau current entirely stops up-river traffic. The Elbe on the other hand has only a small fall and a comparatively weak current.

The waterways are maintained and managed by the Austrian State, which spends about 8 million francs (£320,000) per year for the purpose and levies no tolls.

A large project, involving an expenditure of about 800 million (£32 millions) has been brought forward for building canals connecting the Danube with the Oder and with the Elbe, and for canalizing the Moldau. Its execution is problematical.

In the table below we give statistical data about the traffic on three chief Austrian waterways in 1905 :

WATERWAY.	Total tonnage (in millions of tons).	Down-river tonnage (in millions of tons).	Up-river tonnage (in millions of tons).	Tonnage, steamships (in millions of tons).	Ton-kilometres, millions (English ton-miles, millions).	Mean distances carried (in kilometres [in miles]).
Danube	1·8	0·9	0·9	1·3	260 (159)	139 (86)
Elbe	3·9	0·6	3·3	3·5	152 (93)	83 (24)
Moldau	1·2	0·09	1·1	0·8	42 (26)	34 (21)
Total, Austrian waterways	7·2	...	...	5·5	486 (297)	67 (42)

The predominating part played by steamships has to be noted. The Moldau traffic is diminishing during the last few years. The chief item in the Danube traffic is the up-river carriage of Rumanian and Hungarian corn. The Elbe traffic consists nearly wholly of lignite carried from Aussig to Germany.

The mean distances given only correspond to the journey on Austrian territory. If that in other countries were taken into consideration, they would have to be considerably increased, particularly as regards the Elbe and the Danube down-river traffic.

The freight on the Danube and the Elbe varies between 0·6 to 1·4 centimes (0·09*d.* to 0·22*d.* per English ton-mile); it averages 1·1 centimes per ton-kilometre (0·17*d.* per English ton-mile). It is lower on the Elbe than on the Danube. The mixed traffic plays a very important part on the Elbe at the ports of Aussig (coal) and of Tetschen (miscellaneous).

HUNGARY.

A. — *Railways.*

The Hungarian Railway system is altogether 17,000 kilometres (10,564 miles) in length; 7,300 kilometres (4,536 miles) of it are local railways operated by the administration of the State Railway, on account of the owners. This does not include the comparatively-small part of the Austro-Hungarian system, which is on Hungarian territory. The State operates the whole of railways, except about 1,500 kilometres (932 miles).

The standard-gauge main-line and local system cost 3,450 million francs (£138 millions) (900 millions [£36 millions] of which were spent by companies), or 330,000 francs per kilometre (£21,243 per mile).

The goods traffic amounted in 1906 to 5 milliard ton-kilometres (3·058 milliard English ton-miles).

The gross receipts were 365 millions (£14,600,000), the working expenses 221 millions (£8,840,000) and the net profit 144 millions (£5,760,000); this represents 4·2 per cent on the capital outlay.

The Hungarian State levies a tax of 20 per cent on passenger fares, of 7 per cent on quick-freight receipts and of 5 per cent on slow-freight receipts. This tax yielded 25 million francs (£1 million) in 1905.

B. — *Waterways.*

The Hungarian waterway system is altogether 3,100 kilometres (1,926 miles) in length. It consists of rivers, with the sole exception of the Franz canal. This canal is 238 kilometres (148 miles) long; a concession for it was granded in 1870, for seventy-five years, to a company which levies tolls varying from 0·015 to 0·05 franc per ton-kilometre (0·24*d.* to 0·78*d.* per English ton-mile).

The rest of the system is managed by the State which spends about 7 million francs (£280,000) per year on it and levies no tolls for its use.

The most important sections of the river systems are, firstly the Danube, 1,033 kilometres (642 miles); then its tributaries, the Tisza, 461 kilometres (286 miles), the Save, 604 kilometres (375 miles) and the Drave, 229 kilometres (142 miles).

Three quarters of the Danube traffic is up-river traffic (cereals).

The traffic on the whole Hungarian system amounts to nearly 4 million tons and represents about 1,500 million ton-kilometres (917,400,000 English ton-miles).

FRANCE.

I. — Extent. — Geographical situation. — Cost of construction.

A. — *Railways.*

The total length of the general railway system of France in operation on 31 December 1907 was 40,050 kilometres (24,886 miles), which had cost 17,862 million francs (£714,480,000), or 466,000 francs per kilometre (£28,710 per mile).

The cost of construction was made up as follows (before the repurchase of the French Western) :

Expenditure by the State (including repurchases)	5,532 million francs		(£221,280,000).
Expenditure by the companies (not including expenditure made by them on lines subsequently repurchased)	12,089	—	— (£483,560,000).
Expenditure by districts	241	—	— (£9,640,000).
Total.	17,862 million francs		(£714,480,000).

In this we do not include local railways and tramways which also carry slow-freight traffic; at the end or 1907 there were 12,600 kilometres (7,829 miles) in operation, which had cost 840 million francs (£33,600,000).

B. — *Waterways.*

The system of French waterways actually used for navigation proper had the following length in 1907 :

Free-running steams and rivers	3,400 kilomètres		(2,113 miles).
Canalized streams aud rivers	3,600	—	(2,237 —).
Canals	4,900	—	(3,045 —).
Total.	11,900 kilomètres		(7,395 miles).

Of this total, 4,800 kilometres (2,483 miles) are accessible to Flemish canal-boats carrying 300 tons. The canalized Seine, from Rouen to Corbeil (277 kilometres [172 miles]), has a channel 3·50 metres (11 ft. 6 in.) deep and takes vessels carrying 4,100 tons.

Only two rivers (the Rhone and the Seine) are of serious importance as regards water-borne traffic. The first has against it the rapid current caused by its considerable fall, for it has a height of 100 metres (328 feet) at 215 kilometres (134 miles) from the sea; the second its tortuous course, so that it is nearly twice as long as the crow flies.

The expenditure on French waterways (construction of canals, improvement of

streams and rivers), made nearly entirely by the State, may be estimated at 1,800 million francs (£72 millions), 1,600 millions (£64 millions) of which have been spent on works since 1821.

This expenditure is distributed very irregularly over the different waterways. On the principal lines of the system (from Paris to the north, to Belgium and the east, and from the north to the east), having a length of 1,400 kilometres (870 miles) and carrying half the total traffic, the expenditure on building and on improvements hardly exceeds 250,000 francs per kilometre (£16,093 per mile). The most recently constructed routes are the most expensive.

Canal from the Aisne to the Marne	413,000 francs per kilometre	(£26,585 per mile).
— — Marne to the Saone	570,000 —	—	(£36,692 —).
Seine improvements	450,000 —	—	(£28,968 —).
Canal from the Oise to the Aisne	725,000 —	—	(£46,670 —).

II. — Administrative régime.

A. — *Railways.*

Most of the French railways were built by private companies. The State gave them subventions, and these subventions represent nearly the total cost of most of the new lines with little traffic which are built now-a-days. In addition, the State guarantees the companies a minimum revenue; the sums paid under this head are however but advances, repayable when the net receipts exceed the guaranteed revenue. There is in France a State railway system which included 2,800 kilometres (1,740 miles) at the end of 1907 and to which the act for the State purchase of the French Western Railway (13 July 1908) added 5,800 kilometres (3,604 miles).

As against the subventions received from the State, the railways bestow on it several receipts and economies which for the financial year 1907 may be estimated as follows :

Duties on traffic	Passengers (12 per cent of the rates)	74 millions	(£2,960,000).
	Receipt stamps	43 —	(£1,720,000).
Common-law duties on the stock issued by the companies	Stamp	11 —	(£440,000).
	Transfer duties	17 —	(£680,000).
	Tax on revenue	30 —	(£1,200,000).
Economies in the public services resulting from the reductions in the rates or from free conveyance specified in the tariffs	Posts and telegraphs	63 —	(£2,520,000).
	Soldiers and sailors	37 —	(£1,480,000).
	Customs and indirect contributions	3 —	(£120,000).
Net profit of the State system		13 —	(£520,000).
	Total	291 millions	(£11,640,000).

This figure is considerably higher than the total annual charges imposed on the State for the railways during the same period, namely :

Interest on borrowed capital expended on works carried out by the State and on subventions paid in capital	129 millions (£5,160,000).
Annuities paid to the companies for capital supplied by them or for exchanges of lines	79 — (£3,160,000).
Total. . .	226 millions (£9,040,000).

We leave out of consideration the guaranteed interest which is of the nature of an advance; in 1907 (an exceptionally-favourable year), 37 million francs (£1,480,000) were received by the State from three companies, either as repayments or as share of profits, while it paid 16 million francs (£640,000) to four other companies.

The receipts earned by the general railway system of France amounted in 1907 to 1,702 million francs (£68,080,000), as against working expenses of 956 million francs (£38,240,000); the net profit was 746 million (£29,840,000), representing 4·18 per cent on the capital outlay.

B. — *Waterways.*

It is the State which constructs and maintains the waterways.

Those for which concessions had been granted were repurchased in the middle of the 19 th. century, except 250 kilometres (155 miles) which included :

1° The canal from the Sambre to the Oise;
2° The canals of the city of Paris;
3° Sections of no importance.

The cost of maintenance and management amounted to about 19 million francs (£760,000); the land receipts and the taxes yielded about 3 million francs (£120,000).

Since 1880 shipping pays nothing for the use of the waterways; neither on the open line, nor at the locks, nor at the public ports.

An act of 3 July 1900 has authorized the chamber of commerce of Saint-Dizier to levy tolls on the canal from the Marne to the Saone, for constructing which it had borrowed 5 million francs (£200,000). The tolls charged amount to 0·6 centime per ton-kilometre (0·09*d.* per English ton-mile), for any class of goods. The same system will be applied to the Northern canal, on whose construction the chamber of commerce of Douai is going to spend 30 million francs (£1,200,000). The tolls may amount to 1·2 centimes per ton-kilometre (0·18*d.* per English ton-mile) in the case of articles of value.

The Marseilles chamber of commerce, which is going to defray the greatest

part of the cost of the canal from Marseilles to the Rhone, will pay interest on the loan necessary by a toll levied not on the boats, but on the whole traffic of the seaport.

III. — Particulars of the traffic.

We give below (fig. 4) a diagram showing the progress of the traffic on the railways and the waterways.

After remaining practically constant during thirty years (1850-1880), the total traffic on the waterways increased gradually and very regularly from 2 milliard to 5·3 milliard ton-kilometres (1,223 to 3,241 millions English ton-miles). The increase in the first place began in the average distance goods were carried, which grew in five years (1881-1886) from 110 to 133 kilometres (68 to 83 miles), as a result of the unification of the type of locks. During the last twenty years, the increase has chiefly been in the number of tons shipped.

The average length of journey was 154 kilometres (96 miles) in 1907. This figure is slightly lower than the average on railways which is estimated at about 165 kilometres (103 miles); the figure of 127 kilometres (79 miles), given in the statistics, is in fact under the truth, for the statistics are compiled for each railway separately, so that each ton travelling on two railways is counted as two units.

The traffic on the waterways is distributed very irregularly. Geographically considered, the north and north eastern part of France, forming one fifth of the whole country, includes four fifths of the water-borne traffic.

Of the three classes of waterways, we can leave out the traffic on the free-running rivers, which is quite insignificant except in the case of the Rhone, and even there it only amounts to 90 million ton-kilometres (55 millions English ton-miles). The rest of the traffic is divided between the canalized rivers (two fifths) and the canals (three fifths).

The mean tonnage per kilometre of waterway is practically equal in the two latter classes, amounting to about 600,000 tons. This figure is largely exceeded on the Seine (2·5 million tons), on the main line from the north to Paris (3·5 million tons), on that from the north to the east (1·8 million tons), and *a fortiori* on the common trunk of the two latter, the Saint-Quentin canal (5 million tons).

The principal inland port is Paris; the traffic there consisted of 10·5 million tons, made up as follows:

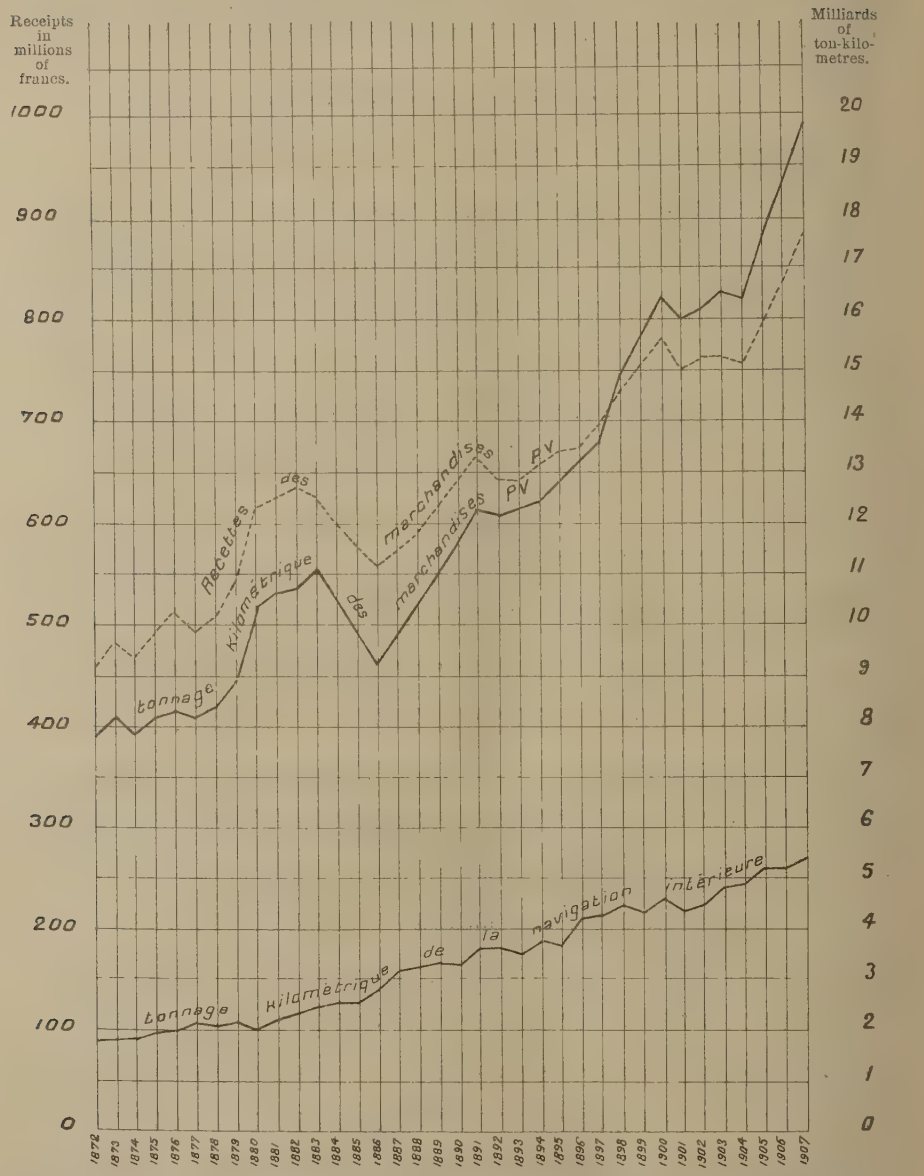
received	2·5 million tons,	transit	1·4 million tons,
despatched	6·3 — —,	home traffic	0·3 — —.

Next come:

Rouen	2·4 million tons.	Albon.	1·1 million tons.
Dunkirk	1·2 — —	Villeneuve St. Georges . .	1·1 — —

Thus there are five ports each with a traffic exceeding 1 million tons; next three

Fig. 4. — **Diagram showing the slow-freight traffic and receipts of the main railroads and the traffic on the waterways of France.**



Explanation of French terms : Recettes des marchandises = Slow-freight receipts. — Tonnage kilométrique des marchandises = Slow-freight traffic, ton-kilometres. — Tonnage kilométrique de la navigation intérieure = Water-borne traffic, ton-kilometres.

are ten ports with a traffic of from 0·5 to 1·0 million tons, and then one hundred ports with a traffic of from 0·1 to 0·5 million tons.

IV. — Particulars of the rates.

It is impossible to give any particulars of the rates charged on French railways; the system of rating is too complicated. We will only recall that on the main lines fixed rates are still numerous, and that differential rates are extensively applied. The scales applied generally include, apart from a constant and rather small amount for terminal charges, a rate calculated according to distance, the rate decreasing as the distance increases; in the case of heavy goods the decrease is quick and the final rate is often very low (2 centimes [0·32*d*. per mile], 1 centime [0·16*d*. per mile] or even less, for every additional kilometre).

We would also mention that in the matter of tariffs, the initiative lies with the railways and the right of confirmation with the minister of public works, who decides after an enquiry, with the advice of the consultative committee of the railways.

The predominating system in the case of French shipping is that of small undertakings. Two fifths of the boats belong to owners who have but one boat and run it themselves. Undertakings of any size (twenty boats or more) only account for one tenth of the total number. The solitary owners are those who carry the large traffic; their freight nearly always consists of one single consignment. The consignor and the consignee attend to the handling of the goods. The competition of the solitary owners determines the rates and reduces them to near the net cost, leaving but little remuneration to the owner; these rates vary on the different lines.

As the normal freight on the lines which are in good condition (north or east), in the direction of the chief traffic and for long distances, we may give 1·2 to 1·5 centimes (0·19*d*. to 0·24*d*. per English ton-mile). In the opposite direction, the return freight, if freight is scarce (leaving Paris or Nancy), sometimes falls to 0·7 or 0·8 centimes (0·11*d*. to 0·13*d*. per English ton-mile).

On the Seine, the normal freight is 1·4 centimes (0·22*d*. per English ton-mile) up river (direction of the heaviest traffic) and 1 centime (0·16*d*.) down river.

On the central and southern canals the freight amounts to 2 centimes (0·32*d*.); on the Rhone, to 3 or 5 centimes (0·47*d*. or 0·78*d*. per English ton-mile).

Finally the large shipping companies, who try to obtain the valuable-article traffic, fix their freight according to the railway rates, granting reductions varying from 10 to 30 per cent, according to case.

During the last thirty years freights have fallen at least 20 per cent in France.

V. — Mixed traffic.

Such traffic is very rare in France.

The total number of tons transhipped from wagon to boat or from boat to wagon

amounted to about 800,000 tons (or 0·5 per cent of the total railway tonnage), about half of which was transhipped at the port of Roanne.

The transhipping traffic at that port in 1907 was made up as follows :

From wagon to boat .	208,000 tons including	145,800 tons of pyrites going from Saint-Bel to Paris. 42,200 tons of mineral waters going from Saint-Galmier, etc., to Paris. 14,600 tons of coal, etc.
From boat to wagon .	128,500 tons including	36,000 tons of sand and stone from Nemours. 21,000 tons of coal. 15,600 tons of iron and cast iron.
Total. . .	336,500 tons.	

We may also mention the ports of Monluçon and Ivry on the Orleans system, and those of Varangéville and Giraucourt on the Eastern system.

BELGIUM.

I. — Extent. — Cost of construction.

A. — *Railways.*

At the end of 1907, the total length of the general railway system operated in Belgium was 4,600 kilometres (2,858 miles), which had cost 2,660 million francs (£106,400,000), or 570,000 francs per kilometre (£36,692 per mile), not including the suburban railways, 3,000 kilometres (1,864 miles) of which were being worked.

B. — *Waterways.*

The waterways are altogether 2,000 kilometres (1,242 miles) in length, made up of : free-running rivers, 500 kilometres (310 miles); canalized rivers, 550 kilometres (342 miles); canals, 950 kilometres (590 miles).

A large part of the system was built at the beginning of the 19th century. The amount spent on construction from 1831 to 1907 amounted to about 400 million francs (£16 millions).

II. — Administrative regime.

The State owns and operates more than 4,000 kilometres (2,485 miles) of the 4,600 kilometres (2,858 miles) forming the main railroad system of Belgium.

In 1907, the gross receipts (taxes not included) of the main railroad system were 299 million francs (£11,960,000), and the working expenses 200 million francs (£8 millions). The net profit, 99 million francs (£3,960,000), represents 3·72 per

cent on the capital outlay, and this approximately covers the financial charges. If we only consider the State system, the net receipts (82 million francs [£3,280,000]) are little lower than the financial charges.

Except in the case of a very few provincial and communal canals, and canals for which concessions have been given (Blaton to Ath, Brussels to the Rupel), the waterways are maintained by the State. The toll principle is applied generally in Belgium to the waterways, except on the tidal Scheldt and its tributaries, the middle Meuse and some secondary waterways. The tolls charged, reduced and unified in 1886 after long discussions, amount normally to 0·16 centime per ton-kilometre (0·025*d.* per English ton-mile) on canalized rivers and to 0·5 centime (0·08*d.*) on the canals.

These tolls yielded 2,200,000 francs (£88,000) in 1907, thus practically paying for the expenditure incurred by the State on maintenance and working in the same year (2,300,000 francs [£92,000]).

The receipts and expenses of the Belgian State for the waterways are given, in millions of francs, in the following table :

PERIOD.	Cost of maintenance.	Cost of construction.	Receipts.	Difference between the receipts and the cost of maintenance.	
				plus.	minus.
From 1831 to 1840 . .	4·5 (£180,000)	9·4 (£376,000)	13·8 (£552,000)	9 3 (£372,000)	...
From 1841 to 1850 . .	12·6 (£504,000)	17·7 (£708,000)	28·8 (£1,152,000)	16·2 (£648,000)	...
From 1851 to 1860 . .	14·7 (£588,000)	37·1 (£1,424,000)	29·7 (£1,188,000)	15 (£600,000)	...
From 1861 to 1870 . .	14·3 (£572,000)	62·2 (£2,488,000)	21·5 (£860,000)	7·2 (£288,000)	...
From 1871 to 1880 . .	22·9 (£916,000)	90·2 (£3,608,000)	16·7 (£668,000)	...	4·2 (£168,000)
From 1881 to 1890 . .	23 (£920,000)	70·3 (£2,812,000)	14·8 (£592,000)	...	8·2 (£328,000)
From 1891 to 1900 . .	20·8 (£832,000)	46·2 (£4,848,000)	20 (£800,000)	0·8 (£32,000)	...
From 1831 to 1900 . .	112·8 (£4,512,000)	333·1 (£13,324,000)	145·3 (£5,812,000)	36·1 (£1,444,000)	...
	445·9 (£17,837,000)				
In 1907	2·3 (£92,000)	10·5 (£420,000)	2·2 (£88,000)	...	0·1 (£4,000)

III. — Particulars of the traffic.

The statistics do not give the mileage on the Belgian railways.

The carriage of the goods classified as " grosses marchandises ", which very nearly correspond to what we call slow-freight in France, supplies 57 per cent of the receipts, corresponding to 71 million tons, an increase of 29 per cent as compared with 1900 (55 million tons).

On the waterways the traffic increased to 52 million tons. The average distance each ton was carried (in Belgium) was only 23 kilometres (14 miles). The number of ton-kilometres amounted in 1907 to 1,200 millions (734 millions English ton-miles), an increase of 35 per cent as compared with the figure for 1900 (894 millions [547 millions English ton-miles]).

One fourth of this total is however composed of canal-boat traffic on the estuary of the Scheldt, below Antwerp, which can hardly be considered an inland waterway.

Next to the Scheldt, the busiest lines are the canalized Meuse, the canal joining the Meuse and the Scheldt, the Sambre, the canal from Maestricht to Bois-le-Duc and the upper Scheldt, which together give about 500 million ton-kilometres (306 millions English ton-miles).

The steam traffic (steam barges or steam tugs) is important; it amounts to 450 million ton-kilometres (275 millions English ton-miles), half being on the estuary of the Scheldt.

IV. — Particulars of the rates.

The railway tariffs are in the form of scales of differential rates. Taking them altogether, they are appreciably lower than those applied as a rule in Germany and France. They differ but little from those applied on the French Northern Railway.

The freights on the Belgian waterways vary much (0·5 to 4 centimes per ton-kilometre [0·08*d.* to 0.64*d.* per English ton-mile]) according to the dimensions of the boats they can accommodate, the season, and the length of journey.

There is practically no mixed traffic.

HOLLAND.

A. — *Railways.*

The railway system was 3,400 kilometres (2,113 miles) long at the end of 1907. The capital outlay is unknown to us; it represents 861,000 francs per kilometre (£55,425 per mile) in the case of the Dutch Railway Company.

The greater part of the railway system has been built by the State, the rest by companies. The usual system of operation is that of leasing, with division of gross receipts. In 1906 the receipts amounted to 122 million francs (£4,880,000), the expenses to 89 million francs (£3,560,000) and the net profit to 33 million francs (£1,320,000). The companies can fix their own rates; the State only sees that the legal maximum is not exceeded. These rates are moreover low, owing to the competition of the network of canals extending over the whole country. The goods traffic amounted to 1,250 million ton-kilometres (764 millions English ton-miles).

The waterways have a total length of 5,200 kilometres (3,231 miles), made up of 2,000 kilometres (1,242 miles) of rivers and 3,200 kilometres (1,988 miles) of canals.

The rivers are maintained and managed by the State.

The canals have three different origins :

1° The canals specially built for purposes of navigation, which are of but little importance if we leave the sea canals (North Sea canal, Amsterdam to Ymuiden, and Terneuzen) out of consideration;

2° The old draining canals, sometimes very wide and rather deep, on many of which there is a busy steam traffic. To this class belong the Amstel and the Spaarne, which have a depth varying between 2·20 and 3·70 metres (7 ft. 3 in. to 12 ft. 2 in.), and a width varying between 40 and 250 metres (131 to 804 feet);

3° The canals excavated more recently in the provinces of Friesland, Groningen, Overyssel, and Drenthe, for carrying peat.

One tenth of the Dutch canal system belongs to private owners, two tenths to the State, three tenths to the provinces, four tenths to the communes or corporations.

The State did not contribute to the capital outlay till after 1840.

From 1850 to 1900, it has apent 300 million francs (£12 millions) on the improvement and maintenance of waterways; nearly half of this sum was more especially for the benefit of sea traffic. The rivers are free; on the canals varying tolls (0·25 to 1 centime per ton-kilometre [0·04*d.* to 0·16*d.* par English ton-mile]) are charged, generally levied when passing locks or bridges; but the yield of these tolls does not cover the cost of maintenance of the canals. Tolls have recently been abolished on State canals, but they still exist on most of the others.

SECOND PART.

Factors which influence the distribution of the traffic between railways and waterways.

We must in the first place make an important remark : the competition of waterways, even in a country where they are much developed, can never affect more than a fraction of the railway traffic.

Passenger and parcels traffic avoids waterways nearly entirely, as does the greater part of the broken-load slow-freight traffic. On the other hand, it is just because the railway does work which no other means of communication can do, that modern States desire to have railways in all parts of their territory, both those accessible to shipping and those which are not. It follows from this that for geographical reasons the waterway system is generally much less extensive and above all much less regularly distributed than the railway system.

In short, railways can compete with waterways everywhere and for every class of traffic (1), whereas the inverse is not true. It follows that, in the question which we are considering, railway statistics cannot be utilized except with the greatest caution, because they include, not only the elements of a service comparable with a waterway service, but also elements of a totally different nature.

I. — Cost of carriage.

The cost of carriage is generally the chief factor in questions of competition. Unless there are special reasons to the contrary, the consignor gives the preference to the cheapest way.

We shall see that the most disputed articles are heavy goods consigned in large lots. On many of the waterways, they form nearly the whole traffic. Consequently if we wish to compare railway rates with waterway rates, it is necessary, in order to obtain a proper comparison, to take the corresponding rates for consignments consisting of train-loads, or at least of a set of truck-loads, the handling being at the cost of the customer.

The system of rating is of great importance as regards the division of the traffic. We shall see that waterways will obtain a share of the traffic which will be the greater the longer the distance the goods are carried. The railway tariffs which compete most advantageously against waterways will accordingly be those which give the lowest rate for the longest distance, that is to say those in which the rate

(1) The Volga excepted, along which there is as yet no railway.

per kilometre decreases rapidly as the distance increases. They make it above all very difficult to have mixed carriage, when the destination itself is not on a waterway; that part of the journey which must then be necessarily effected on the railway will in such a case become much more costly, as it will be rated as a *separate* journey paying a price based on the high initial rates, and not as *additional kilometres* on which a very low rate is paid. It is for this reason that the German system of tariffs, in which prices are proportional to the distance (equal mileage rates), is more favourable to the waterways than the French and the Belgian systems, which include scales of differential rates. The mean height of the rates depend moreover to a large extent on the sacrifices the different States make on behalf of their railways, or on the other hand, on the burdens they impose on them. The same applies to the waterway rates. The first part of this paper shows (except perhaps in Holland) that the railways are seriously handicapped in this respect as compared with the waterways. Goods carried on the railway have to pay : 1° the maintenance of the track ; 2° the capital charges, and moreover in many cases earn for the operator (State or company) a profit which may be considerable (in Prussia for instance) ; goods carried on railways are nearly always freed from the two latter items and only pay a small fraction of the first, when they are not freed altogether.

Apart from tolls, the factor which has the greatest influence on the cost of carriage on waterways, is the *true value of the way from a technical point of view*.

a) One of the disadvantages of a waterway is that it presents, as compared with a railway, a *longer journey*, for it has to go round obstacles which a railway can go through, and it has generally to follow the bottom of valleys. This lengthening does not exceed 17 per cent in the case of the two large German rivers, from Rotterdam to Mannheim or from Hamburg to the Austrian frontier. It is greater in France and attains :

From Paris (La Tournelle)	to Nancy	17 per cent.
	to Dijon	26 —
	to Lyons	25 —
	to Dunkerque	48 —
	to Valenciennes	26 —
	to Rouen	78 —

b) A small fall is favourable to navigation. We can easily classify the chief continental rivers from this point of view by stating that a height of 100 metres (328 feet) above sea-level is attained at the following distances from the mouth :

Rhone	215 kilometres	(134 miles).	Rhine	621 kilometres	(386 miles).
Loire	398 —	(247 —).	Elbe	662 —	(411 —).
Oder	524 —	(326 —).	Danube	1,725 —	(1,072 —).
Seine	556 —	(345 —).	Volga	2,490 —	(1,547 —).

c) On canals and canalized rivers, the fall shows itself by the number of locks, which are a cause of delay. Now every loss of time involves an increase in the freight; for if the distance the boat travels during a year is reduced, it is necessary that every kilometre covered should yield a greater fraction of the remuneration of the crew and of the interest on the capital outlay. The number of locks varies greatly with the topographical situation; the proposed canal from the Rhine to Hanover will only have 8 locks on a length of 310 kilometres (193 miles), while the Marne to Rhine canal has 177 locks for the same length.

If there are many locks, it is not possible to give them large dimensions without excessive capital outlay. They then can hold only one barge (this is the case on French canals), and consequently haulage by tugs becomes impossible.

d) The small size of the locks moreover makes it impossible to use large boats. Now, other things being equal, the freight varies inversely as the tonnage. Large boats realize important economies, for the cost of traction and of staff increases at a much lower rate than the load. We find great differences in this respect, between the Berry 80-ton barges and the great 9,000-ton petroleum boats on the Volga.

e) The navigation is interrupted by being stopped. Voluntary stoppages, for facilitating the execution of works, are becoming rarer and rarer. But ice has always to be taken into consideration; this stops navigation a month in the east of France and the west of Germany, two months in the east of Germany and five months in Russia.

Finally in Germany, low water has to be taken into consideration; its duration and extent are very variable in different years, and often results in high freights; sometimes the traffic is even stopped altogether. Thus the Rhine at Strasburg was navigable 160 days in 1904 and 268 days in 1905, so that the traffic at that port amounted to 415,000 and 807,000 tons respectively. The interruption of the navigation, making it necessary to cover the fixed charges of the boats while effecting a smaller number of voyages per year, naturally leads to a general rise in freights to which one has to add the inconvenience suffered by the customers.

f) The freight largely depends on the organization of the traction. The old motive powers, men, horses, donkeys, are being replaced more and more by mechanical motors which are faster, more regular and particularly advantageous when traction can be applied to entire trains.

If we summarize all these considerations, we must conclude that a good canal is worth more than a poor river, but that it is very inferior to a good river. The freight may come down to 1·5 centimes (0·24*d*. per English ton-mile), to 1 centime (0·16*d*.) and even to a little less on a good canal; but only on a great river, with important traffic, where trains of boats carrying several thousands of tons are hauled, is it possible to obtain those freights of 0·4 to 0·05 centime (0·06*d*. to 0·08*d*. per English ton-mile), which the economists admire on the Rhine and the Volga.

We have spoken of freight as if it were a well-defined quantity. Actually it is however only an average, for freight is subjected to many fluctuations during the year :

1° Freight varies, for the same article, on the same river, with the height of the water, for if this is low, the boat may only be able to take a reduced cargo. This cause of variation is particularly appreciable in Germany and Russia; the rise it causes in freights attains and even exceeds 50 per cent at certain periods. Thus for instance the freight on cereals, from Antwerp to Strasburg, which is usually 5·50 francs (4*s*. 5·6*d*. per English ton., rose to 8·75 francs (7*s*. 1·3*d*.) during the month of January.

2° Freight is largely influenced also by the law of supply and demand. The freight on coal, for instance, always rises during the winter, at the time when the need for coal most makes itself felt; it is on the contrary very low in summer.

During August 1907, the freight from Charleroi was 6·75 francs (5*s*. 5·8*d*. per English ton to Rheims, 7·25 francs (5*s*. 10·7*d*.) to Nancy and 7·70 francs (6*s*. 3·1*d*.) to Epinal; in March of the same year it had been 7·25 francs 5*s*. 10·7*d*.) to Rheims, 8·25 francs (6*s*. 8·5*d*.) to Nancy and 8·75 francs (7*s*. 1·13*d*.) to Epinal. The same fluctuations were observed in case of coal brought from the north to Paris; the freight was 6·25 francs (5*s*. 1*d*. in January, October, November and December 1907, and only 5 francs (4*s*. 8*d*.) in the summer months of the same year.

Sometimes the variations are even greater : in 1906, the Seine boats were unable to cope with the English coal which had arrived at Rouen, and the freight from Rouen to Paris suddenly rose from 3 to 5 francs (2*s*. 5·3*d*. to 4*s*. 0·8*d*. per English ton).

There is, however, a whole class of water-borne traffic the charges for which are nearly fixed and which are not immediately affected by the law of supply and demand. This is the carriage of articles of value effected by large shipping companies running regular services. We shall see further on that these companies hardly ever compete against each other, and chiefly strive to take away from the railways traffic in articles which can bear high freights, by offering a definite reduction on the railway rates, determined so as to allow for the lesser facilities offered to its customers.

We stated at the beginning of this chapter that in most cases a better rate is a sufficient reason in the choice of one of two competing systems of carriage. Nevertheless the railway has as compared with its competitor important advantages such as quickness, regularity and safety. It is generally admitted that the traffic does not become diverted until the difference of rate, in favour of the waterways, attains 15 or 20 per cent. But that is only an average figure, and we shall be able to mention several cases where competition exists, owing to peculiar conditions, although the difference in the rates is far removed from the 20 per cent which it has been desired to fix as an absolute rule.

II. — Terminal charges.

On the railways, the amount of the terminal charged is fixed in the official and permanent tariffs. In France, 30 centimes per ton (2·93*d*. per English ton) must be allowed for the loading and also for the unloading of truck-loads. The German tariffs are a little higher, but the parties interested or forwarding agents nearly always attend to the handling.

On the waterways, the loading costs about 20 to 75 centimes (2·93*d*. to 7·32*d*. per English ton) and the unloading 50 centimes to 1 franc (4·88*d*. to 9·76*d*.).

If one wishes to compare direct carriage by rail with mixed carriage (rail and water), the cost of transhipment has also to be taken into consideration. We give below, as an instance, the amount charged at different tranship ports which are well equipped.

	From wagon to boat.	*From boat to wagon.*
Saxon State Railway (Dresden or Riesa) .	0·50 to 0·70 franc per ton (0·88*d*. to 0·83*d*. per English ton).	0·90 to 1·00 franc per ton (8·78*d*. to 9·76*d*. per English ton).
Baden — — (cereals)	1·00 franc per ton (9·76*d*. per English ton).	0·80 franc per ton (7·80*d*. per English ton) (in bulk). 1·10 franc per ton (10·73*d*. per English ton) (in sacks).
— — — (coals)	0·90 franc per ton (8·78*d*. per English ton).	0·90 franc per ton (8·78*d*. per English ton).
Bavarian State Railway (cereals at Würzburg)	0·60 franc per ton (5·85*d*. per English ton).	0·75 franc per ton (7·32*d*. per English ton).

As a rule, the rail or water carriage has to be supplemented by cartage from the port or station to the manufactory. Cartage, the cost of which increases with the distance, is a heavy charge on the manufacturer. It often restrains him from taking full advantage of boom times, for his supply of horses is limited. In order to eliminate these two disadvantages and to benefit moreover by the advantages of automatic unloading methods, manufacturers have sidings in connection with the railway. This adaptability of iron roads, which enables them to run to each works and even to each part of a works, forms also one of the points in which railways are much superior to waterways.

The French railways have not failed to see the advantage they could draw from this adaptability. The French Northern Railway, in particular, has much facilitated the construction of private sidings, by advancing manufacturers the capital necessary, by doing away with the sidings charges in many cases and by building at its own expense, in the suburbs of large cities, principal lines from which a series of sidings branch. As a result, the French Northern had 1,100 private sidings in 1908, as against 605 stations for the general slow-freight services.

The influence of such sidings in enabling cartage between station and works to be

eliminated, is shown by the following table, for 1906, referring to the Charleville district :

—	Total tonnage dispatched and received.	Tonnage dispatched and received by water.		Tonnage dispatched and received by rail.	
		Total.	Per cent.	Total.	Per cent.
Works with sidings	533,600	75,500	14	458,100	86
Works without sidings . . .	171,400	72,300	42	99,100	58

This advantage of the railways disappears if the establishment concerned is located on the banks of the waterways, so that either method of conveyance can be used without cartage. This is generally the case with the works in the districts of Nancy and of the upper Marne, and this explains that although they have sidings in connection with the railway, the waterway receives a considerable part of their traffic (1906).

Connected works in the district of	Total tonnage dispatched and received.	Tonnage dispatched and received by water		Tonnage dispatched and received by rail.	
		Total.	Per cent.	Total.	Per cent.
Nancy	4,308,400	1,348,400	31	2,965,000	69
The upper Marne	788,300	259,200	33	529,000	67

The influence of railway sidings also makes itself felt in Holland, where the competition of railways is much more acute in the small towns, which often are not served by the railway, than in large towns (Amsterdam, Rotterdam, etc.), where all the works are connected with the railway, and where, on the contrary, the needs of the town traffic tend to close certain canals.

III. — Length of the journey to be effected.

Is the competition of waterways independent of the distance?

In answering this question, we have to remember that the cost of carriage by water, as well as that of carriage by rail, includes a part which is independent of the distance and dependent on the loss of time during loading and unloading; its relative importance decreases as the distance increases. This loss of time is especially important in the case of shipping, as these operations are generally slow and immobilize the staff as well as the boat.

Thus for instance, at one and the same time, the following freights were quoted at Hamburg for the conveyance of 100 kilograms of cereals to the following ports :

Magdeburg	(293	kilom.)	[182	miles].	0·81	franc	or 2·7	centimes	per ton-kilom.	(0·42*d.*	per	Engl.	ton-miles).
Dresden	(566	—	) [352	—	]. 0·90	—	or 1·6	—	—	(0·25*d.*	—	—	).
Aussig	(654	—	) [406	—	]. 1·06	—	or 1·4	—	—	(0·22*d.*	—	—	).

The rate for the freight per unit of distance thus diminishes very appreciably as the distance increases, and the total saving which can then be effected by water carriage becomes sufficiently large to outweigh all its disadvantages.

Thus normally, the competition of the waterways makes itself more strongly felt at long distances.

It is in Germany that this phenomenon is most clearly marked. Water carriage, on the large rivers without locks or on canals with but few locks, is quick; the terminal charges accordingly represent a correspondingly greater part of the total freight. On the other hand, the normal or special rates of the railways are in most cases strictly proportional to the distance. Thus Mr. Sympher has calculated that a consignment would benefit by utilizing the new canal from the Rhine to Hanover as soon as it has to travel more than 40 kilometres (25 miles), if the starting point and the arrival point are on the banks of the canal. If one of these two points is not immediately on the canal, mixed carriage would not become advantageous until the distance exceeded 70 kilometres (43 miles), and if two transhipments were necessary, only when it exceeded 160 kilometres (100 miles).

The preceding consideration explains how it is that the average distance consignments are carried is generally shorter on railways than on waterways. The difference as a rule exceeds the extra length, referred to above, of the waterway between any two given points; whence we may conclude that it influences the traffic more the further distant the localities concerned are from each other.

Thus in Russia, the average distance is 475 kilometres (295 miles) on railways and 950 kilometres (590 miles) on waterways; in Germany, the average distance is 114 kilometres (71 miles) on railways and 290 kilometres (180 miles) on waterways.

In France, the phenomenon is less clearly marked, for two reasons : firstly the freight on our waterways is not as low as in Germany and in Russia; on the other hand, the railway tariffs include largely-differential rates. Certains rates (minerals) are lower than even our lowest freights. The average distance on the waterways is 154 kilometres (96 miles), practically equal to that on railways, if we correct for the fact that the statistics count each ton travelling on two railway systems as two tons.

If, however, we examine certain routes more closely, we still find a certain preference of waterway traffic for long distances; the comparison for the chief articles forming the traffic on the Eastern system is given below.

—	Average distance. in kilometres (in miles)	
	by railway.	by waterway.
Salt to other stations on the Eastern system	266 (165)	428 (266)
Salt to stations on the Northern system	348 (216)	477 (296)
Cereals	70 (43)	157 (98)
Minerals	14 (8·6)	281 (175)

The following table, compiled by the French Eastern Railway, shows, for both methods of conveyance, the average distance coal is carried between Nancy and the different coal-fields supplying that district. This table shows that the distances are greater on the waterways than on the railways; but the difference is not appreciably greater than that resulting from the tortuous nature of the waterways.

Coal and coke. — Year 1907.

Although usually favoured for longer distances, it must not be thought that waterways cannot be suited to medium or even short distances. But then the point which decides the question is not the comparison of the *cost of carriage* proper, but the difference in the *terminal charges*. In this case, the waterway can only compete when it connects two concerns both located on its banks. Such is the case, mentioned by the Orleans Railway, for lime carried from La Guerche to Bourges or Vierzon. The Midi Railway mentions the traffic between the Montech paper-mill and Dieupentale station, which really forms a sort of water-cartage for goods intended for the railway.

However, even in the case of establishments on the banks of waterways, it can happen that the railway still competes for shorter distances, thanks to a perfect organization of the private sidings and of the unloading installations. This is what happens in the case of minerals from the Nancy district, which are carried in large quantities 560,000 tons in 1906) on the railways, over the very short distance (14 kilometres [8·3 miles]) between the mines of Landres, Pompey, Marbache, and the blastfurnaces at Jarville, Maxéville, Pont-à-Mousson, Pont-Saint-Vincent, although there are waterways at all these points. The preference given to the railway is explained by the need of bringing the goods to the boat or taking them from the boat on the very banks of the canal, while a wagon can fetch it from any point on the mine or in the works.

IV. — Time required for the journey.

The advantage of the railway is generally very marked, particularly if we consider not the legal time the railway may take, but its ordinary time, which is appreciably shorter.

On the French Northern Railway, the legal time as a rule does not exceed three or four days, unless the goods are rated under a special tariff allowing an extra five or ten days. As a matter of fact, the traffic department of that railway makes every effort to reduce the time of delivery between all important centres. Thus goods sent from Paris one day are ready for the public the next day at Lille, Valenciennes, Arras, Laon, etc. The same applies to coal trucks brought in the evening to the coal-yards. If these coal trucks are going to Paris, they are taken in eight hours by through trains which are not altered in any way or stabled during the journey.

The same journey by water requires at least fifteen days of travel. In fact the loss of time, either on the way, or while loading and unloading operations are going on, prevents a canal-boat from making more than four journeys per annum, although it has often been asserted, and with reason, that theoretically it could and should make five or six.

The advantage of the railway generally increases with the length of the journey.

Coal from the north going to	Time normally required for the journey	
	by rail.	by water.
Reims	2 days.	20 days.
Saint-Dizier	3 —	30 —
Epinal	4 to 5 —	50 to 60 —

The very long time required for water carriage makes their competition for the passenger and parcels traffic less and less serious.

Exceptional conditions are required to enable waterways to play any part in the conveyance of passengers. The case only arises on certain rivers on the Continent, on those sections which are accessible to large steamships. We may mention the use of the small river-steamers in large towns, the classical excursions on the Rhine, the long-distance services of the Danube Steam Navigation Company (which still carried 500,000 passengers in 1898, after having reached 1,800,000 passengers in 1890), and finally the long journeys on the Volga, where there are 400 fast steamships of up to 1,500 horse-power, capable of carrying 1,400 passengers and covering the 2,200 kilometres (1,367 miles) from Nijni-Novgorod to Astrakhan in five days.

As regards goods, quick-freight services by water are equally exceptional. Well-equipped services of this kind are however found on the large German and Austrian rivers. These services are operated by important steamship companies. They receive the quick-freight goods in small consignments, of from 50 to 1,000 kilograms (110 to 2,200 lb.).

The carriage of quick-freight separate packages only forms an unimportant fraction of the traffic at the upper Rhine ports (about 1 per cent); on the other hand, it forms nearly one third of the traffic at the middle Rhine ports (Cologne, Dusseldorf, etc.), leaving coal out of consideration. We may mention a daily service, in each direction, between Cologne and Rotterdam, leaving at 8 p. m. and arriving the next day at 3 p. m. on the down and at 5 p m. on the up journey. Another service between Rotterdam and Duisburg takes twenty-four hours up and fourteen hours down. This considerable speed enables the shipping to carry part of the traffic in more delicate goods, such as eggs and milk.

Quick-freight services are even more important as regards the Elbe shipping. The two most powerful shipping companies on that river (the " Vereinigte Elbeschiffahrts-Gesellschaften-Aktiengesellschaft " and the " Oesterreichische Nordwest-Dampfschiffahrts-Gesellschaft ") have formed a combine. They run fast boats, of 100 to 300 horse-power, to operate three parcels services :

1° Between Hamburg and Magdeburg and vice-versa; tariff of 25 March 1904; at least three journeys in each direction per week (Monday, Wednesday, Friday);

2° Between Hamburg and the Saxon ports (Riesa and Dresden) and vice-versa; tariff of 1 April 1904; at least three journeys per week in each direction; leaving Hamburg on Tuesday, Thursday and Saturday, and Dresden on Monday, Wednesday, Friday;

3° Between Hamburg and the ports on the upper Elbe : Laube and Tetschen; tariff of 15 January 1903; at least three departures per week from Hamburg and from Tetschen; on Tuesday, Thursday, Saturday.

The conditions and rates for quick-freight conveyance are given in official tariffs which consider three or four hundred different articles. Each rate is composed of two parts :

1° The freight proper (increased by 20 per cent when the water is low), varying principally with the space occupied, which depends on the specific gravity of the goods;

2° The insurance, varying with the value and the risk of damage to the goods, and equal on the average to 50 per cent of the freight.

Very complete and very precise regulations define the rights and the duties of the consignors and of the carriers. The tariffs are as a rule rather high; they generally exceed 3 centimes per ton-kilometre (0·47*d.* per English ton-mile) in either direction. This explains why these services are not utilized for large consignments; the truck-load rates of the railways are in fact generally cheaper, as soon as the consignments amount to 10,000 kilograms (22,000 lb.).

The journey from Laube to Hamburg, 630 kilometres (391 miles), takes three days down; the up-journey takes eight days. We accordingly see, that as far as long-distance traffic is concerned, the fastest waterway services, which may be as quick as the slow-freight railway services, are never as fast as the quick-freight railway services.

The canals of western Europe, being of small cross-section and having numerous locks, are not suitable for quick traffic. We may however mention the organization of the parcels traffic on the canal from Brussels to the Rupel towards Antwerp and vice-versa, where there is a daily steamship service. The goods carried by this accelerated service arrive at their destination the day after they have been handed to the shipping company. The latter also undertakes, when asked by its customers, to collect and deliver the goods at domicile. The freights, which are appreciably lower than the railway rates, vary from 30 to 50 centimes per 100 kilograms (2*s.* 5·3*d.* to 4*s.* 0·8*d.* per English ton) (according to size and consignment) for the carriage from quay to quay. Collection at domicile costs 30 centimes per 100 kilograms (2*s.* 5·3*d.* per English ton).

Leaving out of consideration these very exceptional accelerated services, we have to record that in the case of ordinary slow freight in barge-loads, the time of delivery is very variable, according to waterway. On our French canals, the daily progress of the boats varies between 10 and 20 kilometres (6·2 to 12·4 miles). The

Rhine boats take ten days for covering the 700 kilometres (435 miles) from Antwerp to Strasburg (70 kilometres [43·5 miles] per day); the Volga boats take thirty-five days for covering the 2,655 kilometres (1,650 miles) from Astrakhan to Rybinsk (75 kilometres [47 miles] per day).

The slowness of water carriage is a serious inconvenience to the merchants who make use of it. Air, damp, sun, depreciate certain goods; the effect increases with the time. In comparing different costs of carriage, manufacturers often take into account the loss of interest incurred if water carriage is used, being compelled to make their payments earlier as compared with the time at which their goods arrive at the place where they are wanted. According to information supplied by the French Eastern Railway, the corresponding charge, in the case of coal carried by water from the north to the upper Marne, may amount to about 0·35 franc per ton (3·41*d.* per English ton).

As water carriage is not only slow, but also irregular, its use almost necessarily entails the storage of a considerable quantity of goods, to fulfil the functions of a fly-wheel and provide for a regular supply to the industries concerned. The possibility of keeping a stock easily and economically is then an absolute necessity if water carriage is to be used.

It may happen on the other hand, that the time required for the journey may be an advantage to the merchant, instead of an inconvenience. This happens in the case of certain goods, such as imported corn, which arrives in large quantities, sent as soon as gathered and intended to be gradually resold in smaller quantities without any change; the wholesale merchants gain no advantage in receiving it at once and seek to prolong the cheap storage obtained on the boat until the purchaser desires to take delivery.

V. — Nature of the goods.

Certain goods present, by their very nature, special disadvantages or advantages from the point of view of water carriage. Among the goods which suffer if carried by water, we must in the first place mention coal and coke.

a) Coal is a fuel whose calorific value alters very rapidly. A somewhat prolonged exposure to damp air, to sun or to frost produces a rapid disintegration, similar to that produced by the action of heat. A coal company in the north of France has found that after it had been stored six months, screened and picked coal gave 18 to 20 per cent of smalls, and that after one year the proportion of smalls had increased to 30 per cent.

Water carriage, which necessitates more frequent and rougher handling, is for this reason also not favourable to the preservation of the coal. It has been found that rough pit coal, after having been carried from the Pas-de-Calais to Paris by rail, if screened on a 3-centimetre (1 $^{3}/_{16}$ inches) screen, left 70 to 75 per cent of

pieces on the screen, while after it had been conveyed by water, it only gave 55 to 60 per cent.

Finally the dampness of the coal favours its heating, which again impairs its calorific value. This loss may amount to from 5 to 10 per cent, owing to the long time the water carriage takes.

These phenomena have been described in a noteworthy report by Mr. Gruner, submitted to the International Shipping Congress of 1902. This author concluded that in the case of industrial coal for direct consumption, it must be assumed that the extra cost of handling due to water carriage is 1 to 1·25 franc per ton (9·75*d.* to 1*s.* per English ton), and that the losses resulting from the alteration of coal arriving in large quantities, and not as when required, amount to 2 or 3 francs per ton (1*s.* 7·5*d.* or 2*s.* 5·3*d.* per English ton).

According to information personally obtained from Mr. Weyhemmayer, manager of the *Kohlen-Kontor*, the loss of value of the fuel may vary between 5 and 9 per cent, being greatest in the case of house coal and coke, and very low in the case of washed coal.

It must however be remembered that manufactories have to keep a stock, with a view to the occurrence of a strike, and that often the absence of room makes them prefer to have a floating stock. On the other hand, if the consignee is a coal dealer, he utilizes the smalls in the manufacture of briquettes. Finally, the customers of the retailer have no means for checking the value of the coal they receive, with any accuracy, and pay the same price for it in spite of the deterioration which a manufacturer who has to reduce his net cost has to take into account. These circumstances sometimes lead to the preference of waterways in cases where the difference between the rates does not seem to justify this choice.

b) The alteration, chiefly physical, of the coke is generally greater than in the case of coal.

Mr. Gruner considers water carriage disadvantageous unless it results in a saving of more than 2·50 francs (2*s.*) per ton. Mr. de Lespinats, ironmaster at Neuves-Maisons, on the basis of long comparative experiments on the two systems of carriage, estimated this difference at 1·40 franc (1*s.* 1·7*d.*) per English ton a few years ago. Mr. Guérin, member of the Nancy chamber of commerce, who recently repeated this calculation, arrived at 1·90 franc (1*s.* 6·5*d.*) per English ton.

In this connection it may also be noted that the coke which formerly reached the works of the Nancy district (Maxéville, Frouard, Pompey, Pont-à-Moussons, Neuves-Maisons) entirely by water, has nearly entirely abandoned that way. The only notable exception is the supply to one part of the Neuves-Maisons works, which is favoured by an exceptional position.

c) Water carriage can also have certain disadvatages in the case of cereals. Very dry corn travels very well in canal-boats for one or two months without being affected, if the boat is very water-tight. But if it is at all damp and loaded in bulk,

it is liable to ferment and spoil. In any case, water carriage always presents more risks, from the point of view of the preservation of goods, than railway carriage. In order to keep the corn well aired, a certain number of passages are often left, which reduce the capacity of the boat.

Water carriage on the other hand has advantages for millers. Offers of corn do not come regularly to them all the year round, and a boat has the advantage of acting as a floating store, of preventing obstruction at stations and on sidings, of gradual arrival at the mills, so as to avoid sudden rushes of labour.

Water carriage has a notable advantage when it is a question of bringing cereals imported at seaports to the inland centres of consumption. The canal-boats only have to go alongside the importing vessels in order to be fully loaded up. It is even useless to place the cereals in sacks; a double economy results, in loading and in unloading, and transhipment in bulk is effected very economically.

VI. — Value of the goods.

A very general opinion divides goods into two classes; the first, consisting of heavy goods of little value, would naturally use waterways; the second including light and valuable goods, would suit railways.

This distinction has no real basis, as can be easily explained.

Systematically or not, more or less definitely according to case, the system of railway tariffs is based on an estimate of the rate the consignment can pay, according to its value to the consignor. Under normal conditions, this value of the carriage varies in the same way as the value of the goods, so that the latter is the principal basis of classification, and the difference between the rates applied to different articles is often very great.

On waterway, on the other hand, the competition of the shipping reduces the freight down to near the actual cost of the carriage. No doubt this cost increases a little with the greater responsibility and care required in the case of more valuable goods, but the corresponding difference is not great. Consequently in the case of goods of a certain value there is most advantage, from the point of view of cost, to use the waterways, as long as the railways retain their ordinary system of rating and are not led to make special tariffs on the routes where there is competition. This only ceases to be the case if the goods are of very great value, in cases in which a saving of several francs in the cost of carriage does not compensate for the different disadvantages of water carriage. This may thus perfectly apply to goods of medium value.

On the other hand, it is wrong to say that heavy goods do not suit a railway, for in fact it often carries them at the same rate as a waterway, or even at less, when it is satisfied with making a very small profit in order to contribute towards covering its general expenses, as we will show further on.

The table below shows how the traffic on the French waterways was made up in 1907 :

CLASS OF GOODS.	Tonnage of goods shipped (in tons).	Average distance (in kilometres [in miles]).	Total traffic (in ton-kilometres [in English ton-miles]).
1. Mineral fuel	10,965,000	228 (142)	2,504,000,000 (1,531,000,000)
2. Building materials	12,073,000	77 (48)	929,000,000 (568,000,000)
3. Manure and fertilizers	1,570,000	69 (43)	108,000,000 (66,000,000)
4. Raw materials, for metallurgical purposes	1,717,000	191 (119)	328,000,000 (204,000,000)
5. Wood for burning or using — shipped	1,730,000	166 (103)	288,000,000 (176,000,000)
5. Wood for burning or using — rafts	135,000	53 (33)	7,000,000 (4,300,000)
6. Metals and machines	759,000	305 (190)	232,000,000 (142,000,000)
7. Industrial produce	1,156,000	273 (170)	316,000,000 (193,000,000)
8. Agricultural produce and food	4,268,000	145 (90)	618,000,000 (378,000,000)
9. Miscellaneous	329,000	125 (78)	41,000,000 (25,000,000)
Total and mean	34,701,000	154 (96)	5,371,000,000 (3,284,300,000)

The four first classes include heavy goods, almost exclusively. The goods in classes 6, 7 and 8 are often worth 50 to 100 francs (£2·0*s.* 7*d.* to £4·1*s.* 2*d.* per English ton) and must be considered as of medium value. Class 5 may be considered as of either category, as it includes on the one hand wood for constructional purposes, often worth more than 50 or 100 francs per ton (£2·0*s.* 7*d.* to £4·1*s.* 2*d.* per English ton), and on the other hand, wood for burning and scaffolding of lower value. Although the division made is not strict, we may assume that the errors resulting in class 8 from the presence of articles of food of low value, such as beet-roots, etc., and in class 2 from the presence of articles of a higher value (ashlar, hydraulic lime, etc.) compensate each other. The following division may accordingly be considered as very near :

	Ton-Kilometres.	(English ton-miles.)	
Heavy goods	4,061,000,000	(2,484,000,000)	75 per cent.
Goods of medium or higher value	1,310,000,000	(801,000,000)	25 —

The second division is hence far from being negligible.

It is easy to show, on the other hand, what considerable part is taken by the French railways in the heavy-goods traffic; mineral fuel, which represents 32 per cent of the waterway traffic, forms 28 per cent of the railway traffic; manure

represents 4·3 per cent of the waterway traffic and 5·5 per cent of the railway traffic.

Building materials form the most favoured class as far as waterway traffic is concerned; they constitute 35 per cent of its traffic, while forming only 15 per cent of the railway traffic. This is easily explained; for part of the goods of that class (sand, gravel, etc.) are obtained by dredging.

But these general statements include the railway traffic in the purely agricultural districts, where the heavy-goods traffic is negligible in amount; we find the proportion of heavy-goods carried by rail much greater if we limit the comparison to the waterways and the railways of the north.

	Tonnage carried	
	by rail.	by water.
Coal	15,332,640	7,008,000
Building materials	1,656,000	1,572,000
Manure and fertilizers	1,328,000	616,000
Raw materials for metallurgical purposes	817,000	355,000

Among goods of a certain value carried by water, we must in the first place mention corn and wine, particularly if imported by sea; then textiles and soft goods, groceries and finally the 40,000 tons of mineral waters transhipped at Roanne. Some of the goods, such as corn, wine, sugar, cottons, are often sent in full bargeloads. Others are generally in broken loads, and the shipping cannot deal with them unless regular and quick services are organized; two conditions have to be observed :

1° A satisfactory *commercial organization*. A trader will hardly entrust objects of a certain value to an individual boatman, making some journey or other. He must be able to address himself to a responsible shipping company, having boats starting at fixed dates, installations at the large ports, and representatives charged with looking after customers, attending to the handling and if necessary to the cartage. The chief company of the sort in France is the Havre-Paris-Lyons-Marseilles Company. It has succeeded in obtaining the best locations at several ports, and in creating for itself a sort of half-monopoly, which enables it to fix its rates, not according to the net cost, under the compulsion of competition, but according to the railway rates, allowing in the latter varying reductions (10 to 30 per cent) which experience shows sufficient to attract the traffic which can go by water. It sometimes makes contracts with its customers.

2° A *satisfactory speed*. Regular service can accordingly only be operated with

success on lines where travelling is easy, either because there is not much traffic on them, or because they offer exceptional technical advantages. In France the canals in the centre and in the south, and the Rhone and the Saone, can be included in the former class; the Seine belongs to the latter.

An important part of the articles of value is carried on steamboats which can operate a quicker service than ordinary canal-boats. The following table is compiled from the French official statistics for 1907 :

Class of goods.	Weight shipped.		Proportion per mil.	
	Steamboats.	Ordinary boats.	Steamboats.	Ordinary boats.
1. Mineral fuel	99,676	10,865,126	9	991
2. Building material . .	23,913	12,049,168	2	998
3. Manure and fertilizers .	3,405	1,566,304	2	998
4. Wood for burning or for using	64,218	1,800,690	34	966
5. Metal and machines. .	16,491	742,344	22	978
6. Raw materials, for metallurgical purposes	3,003	1,713,659	2	998
7. Industrial produce . .	70,393	1,085,889	61	939
8. Agricultural produce and food	240,603	4,027,257	56	944
9. Miscellaneous . . .	124,726	204,750	379	621
All goods. . .	646,428	34,055,187	18	982

The large German and Austrian rivers are more suitable for the carriage of valuable goods than most of our railways. In Germany, there are powerful shipping companies, representing an invested capital of more than 80 million francs (£3,200,000), who continually improve and add to their boats. They form among themselves more or less permanent combines, which enable them to raise their rates somewhat. They particularly cater for articles of value.

As an instance, let us take one of the chief Rhenish companies, the "Badische Aktiengesellschaft", which possesses a fleet of seventy boats. In 1906 it carried 225,000 tons down river, two thirds of which represented goods of a certain value (cement, phosphates, salt, cables, rails) sent in full boat-loads, while one third consisted of broken loads; its up-river traffic amounted to 400,000 tons, two thirds of which consisted of cereals, and the rest of cement, timber and sundry goods.

The Elbe traffic includes a still greater proportion of articles of value, particularly down river where it is entirely in the hands of a combine formed by two large com-

panies, as mentioned above. These even make contracts by the month or by the year with the manufacturers and traders of Saxony and of Bohemia in order to make sure of their customers. Thanks to this monopoly, the down-river freight is kept much higher than the up-river freight, although the cost of traction is much less. The up-river rates are in fact limited by the competition of individual boats and of a third less powerful company, the " Elbe Dampfschiffahrtgesellschaft ", of Hamburg.

The following are the principle articles constituting the traffic of the Elbe companies, the goods urgently required utilizing the quick-freight services described above.

Up river, we remark colonial goods (cotton, guano, cigars, rice, coffee, cocoa, cochineal, rubber, indigo, silk, tea), foreign goods (cereals, petroleum, sugar), chemical products, provisions (beer, butter, champagne, lemons, honey, margarine, liquors, tapioca) and manufactured goods (bicycles, American agricultural machinery, sewing machines, pianos).

Down river, the chief articles are sugar, paper, cellulose, Bohemian glass, mirrors, bottles, cereals, oils, bent-wood furniture, china, mineral waters, cognac, chocolate, biscuits.

The 1892 International Shipping Congress had placed on its agenda the examination of the comparative functions of waterways and railways. The German reporters, Messrs. Van der Borght and Dr. Landgraf for the Rhine, Mr. Pescheck for the Elbe and Oder, arrived at the same conclusion as we did; on railways as on waterways, heavy goods predominate, but nearly in the same proportion; shipping takes its share of valuable goods.

This opinion has lost none of its accuracy. The Danube in this respect approximates to the German rivers. The chief part of its traffic consists of cereals, going up river. The current prevents the quick progress of boats in this direction, and makes it impossible to carry fresh articles of food long distances, especially plums and flour. Down river, on the other hand, the boats go fast, there is less traffic and the shipping companies cater by preference for articles of value (cotton, iron, etc.). The Danube Steam Navigation Company is the preponderating factor on the Danube. Its traffic consists, to the extent of 40 per cent, of cereals going up river, and to the extent of 40 per cent, of manufactured products going down river.

In short, wherever shipping finds the topographical conditions favourable and has a proper commercial organization, it can compete with the railway for all goods, except those of very high value.

VII. — Characteristics and habits of the " clientèle ".

We have already stated that the railways are just as suitable as the waterways for carrying large consignments. The tariffs for sets of wagon or for train-loads make it possible to form larger units than single truck-loads and better suited to the needs of large manufactories or of wholesale trade. But at the same time, the whole train

*

can be made up, if required, of a number of small parts, so as to cater for all needs. The railway can, if it desires, change the unit according to town and district, reckoning at one point in hundreds of tons, at another in single kilograms. Shipping is much less able to cope with such a divided and varied service. It includes among its customers far fewer retail traders and private persons. It is in this sense that the following sentence may be understood: " To the waterway the merchandise, to the railway the merchant. "

The average size of a consignment sent by water in France corresponds nearly to the full load of a canal-boat, namely 250 to 300 tons. On the French Eastern Railway, which however takes an important share of the industrial traffic, the average weight of each consignment is 3 to 4 tons. If we consider the French Northern Railway, where the heavy traffic predominates, and if we determine the average weight of a consignment of coal, we find that it is between 16 and 17 tons.

It will be remembered, it is true, that the quick services on the Rhine, the Elbe and the Danube, take broken loads; but here again two different things must not be confounded under the same name. On waterways, everything is called a broken load which does not represent a barge-load. Consignments of 5 and even 10 tons are called broken loads, whereas the latter form the ordinary unit (truck-load) in the case of the larger consignments sent by rail.

We give some illustrations of this preference of traders of small or medium importance for railways.

The first example will be a comparison of the corn trade on the Volga and that of St. Petersburg. The corn trade on the Volga is in the hands of very powerful and very rich millers who prefer to reduce to a minimum the time they have to devote every year to their consignments of corn; they accordingly buy the corn in the productive districts of south Russia and store them at the Volga ports; then as soon as they think freight is low and prices are high they have the whole lot brought in one consignment. On the other hand, at St. Petersburg the corn trade is in the hands of much less powerful representatives of Germany, who cannot lock up so much capital at once and consequently are interested in spreading out their consignments and their payments; and accordingly they are customers of the railway.

The Belgian State Railway mentions a similar phenomenon on the Mons canal, where the coal consignments, formerly very large, have become insignificant since the coal trade, which was formerly in the hands of a few very important firms, have become divided up into a number of small firms.

A curious instance of the reaction of commercial habits on the choice to be made between the two ways is mentioned to us by the Bavarian State Railway. This tells us that the Main only plays an insignificant part in the carriage of planks, because the commercial unit of sale corresponds to a truck-load.

The organization of the coal trade in south Germany exercises a marked influence on the importance of the traffic sent by water. We know that in connection with the Westphalia syndicate there has been formed an organization for carrying and

distributing the coal to south Germany, Alsace-Lorraine, Bavaria and Switzerland. The *Kohlen Kontor*, as this organization is called, refuses to sell coal to merchants except by boat. It thus obtains both the profit on the sale of coal and the profit of shipowner. The latter profit is far from negligible. Mr. Peters points out in fact, that the freight for coal from Ruhrort to Mannheim has increased by 1·25 francs per ton (1*s.* per English ton) since the *Kontor* has come into existence.

A similar organization which operates Silesian coal on the Oder, also somewhat favours the waterways.

The German paper the *Zeitschrift für Binnenschiffarht* on the other hand mentions that the Prussian State, which owns some salt works, arranges matters so as to sell salt only in trucks-loads.

Finally we mention that on the Rhine, certain ship owners of Rotterdam, in order to insure that their cargo-boats have profitable cargoes, carry goods on the river at cost price or even at a slight loss, and this favours shipping.

VIII. — Importance of the places of origin and of destination.

As a general rule, goods carried by water are, as far as the greater part of them is concerned, either coming from or going to large towns or important centres; the traffic of secondary towns and ports forms a smaller fraction of the total waterway traffic than the traffic of secondary towns forms as compared with the total railway traffic.

The points from which goods are sent by water are as a rule mining or industrial centres, or large seaports. The places to which coal or raw materials, which form the chief part of the water-borne traffic, are sent, are manufactories generally concentrated in certain districts. Those to which building materials and imported agricultural produce go are the large cities, centres of population. It is rare that small localities possess merchants capable of buying and selling quantities of corn, salt, sugar, petroleum, sufficiently large to form a barge-load.

The predominating influence of the large centres on the waterway traffic explains itself quite naturally, if we think of the considerable number of large towns which became developed on large rivers, at times when artificial ways of communication were very undeveloped and when the banks of those rivers were, as far as the inlands were concerned, the sole points accessible to heavy traffic without excessive expense.

There are exceptions to this general statement. The sugar refineries, which receive their beetroot and their coal by water, are often in the country. Frequently also the point of destination of water-borne traffic is situated where orografical conditions stop navigation. Hence the importance of the port of Cosel on the Oder, of the port of Lauterburg on the Rhine, where Westphalian coal for the south of Germany is unloaded when the water is too low to make it possible to go to Strasburg.

We can give some figures which confirm our statement. The Midi Railway finds

that on the Garonne, nine tenths of the traffic are to or from Bordeaux, and on the Midi canal three quarters of the traffic are from or to the four principal centres.

The French Eastern Railway has compiled an interesting table which we reproduce below and which shows the relative importance of the railway and waterway traffic on the important line between Paris and Strasburg. This table only includes the towns and industrial centres which in 1906 had a traffic exceeding 100,000 tons. We have included with Nancy its industrial suburbs, namely Jarville, Frouard and Champigneulles.

The percentages vary from one station to another; there is nothing abnormal about this, particularly in the case of stations of secondary importance; frequently, in fact, their whole traffic comes from one single works, which according to location and equipment, gives the preference to the one or to the other way. But it must be remarked that taking it altogether, the waterway percentage is considerable and materially exceeds that which one would find for the total traffic of the district by the Eastern Railway, which the company estimates at about 22 per cent. We find that this average is not attained or is scarcely surpassed in the case of even important towns which, not being chiefly industrial, are above all centres of consumption, such as Chalons, Toul, Bar-le-Duc, Vitry-le-François; waterways only share to any large extent in the arrivals.

This is moreover also the case as regards Paris. The table below shows the development of the traffic of the port of Paris as compared with the slow-freight traffic at the Paris stations. The exceptional rush in the waterway traffic in 1899 is explained by the arrival of materials and the carrying away of rubbish in connexion with the Universal Exhibition, on the banks of the Seine. The year 1906 marks the beginning of a probably more durable progression in the arrivals resulting from the development of the consumption of English coal in Paris, which began at the time of the last coal famine and has continued since. As regards the appreciable increase in the dispatches since 1902, this is partly due to the removal by water of material excavated during the construction of the metropolitan railway.

At Berlin, as at Paris, the part played by the waterways is considerable, particularly as regards arrivals. In order to have an exact idea of the situation, we must add the traffic at the neighbouring ports of Charlottenburg to the traffic at the port of Berlin, and to the railway traffic we must add the tonnage of the stations in the immediate suburbs of Berlin (service traffic excluded). Thus for instance for 1903 we obtain the following figures :

	Railways.	*Waterways.*
Total tonnage	9,600,000 tons.	9,157,000 tons.

While the total traffic is about the same in both cases, the arrivals form three quarters of the railway traffic and nine tenths of the waterway traffic.

Place on the Marne and on the canal from the Marne to the Rhine.	Dispatched.					Arrived.					Dispatched and arrived.				
	Total tonnage.	Waterway.		Railway.		Total tonnage.	Waterway.		Railway.		Total tonnage.	Waterway.		Railway.

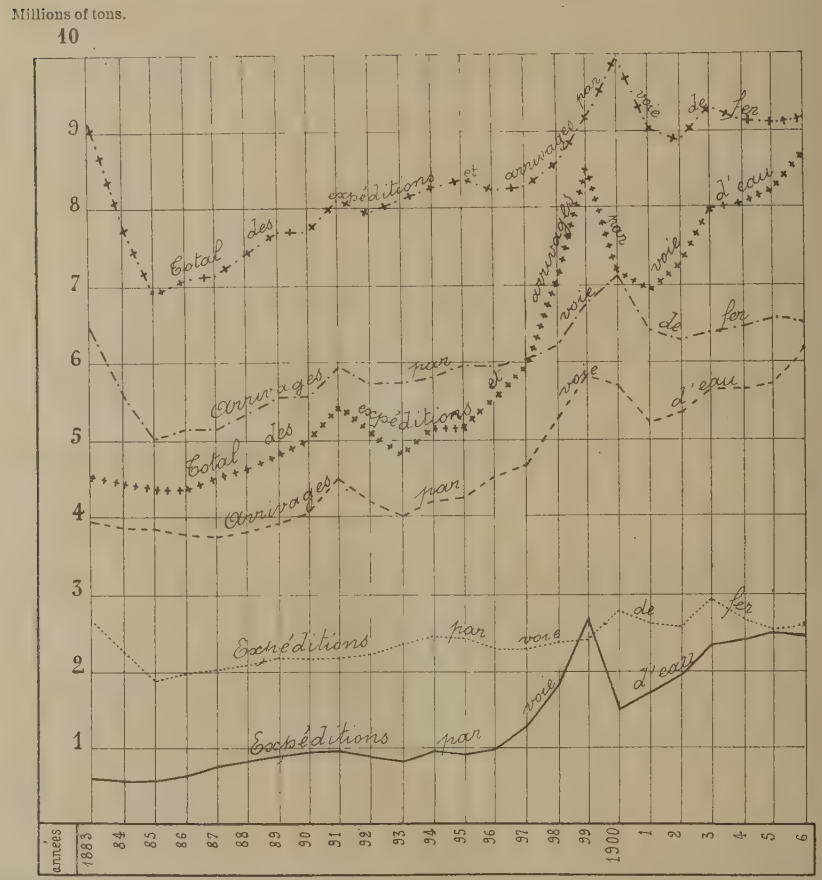
Fig. 5. — **Dispatches and arrival at the port and at the stations of Paris.**



Explanation of French terms : Années = Years. — Total des expéditions et arrivages par voie de fer = Total of dispatches and arrivals by rail. — Total des expéditions et arrivages par voie d'eau = Total of dispatches and arrivals by water. — Arrivages par voie de fer = Arrivals by rail. — Arrivages par voie d'eau = Arrivals by water. — Expéditions par voie de fer = Dispatches by rail. — Expéditions par voie d'eau = Dispatches by water.

We have left out of consideration the transit waterway traffic which attained 1,400,000 tons in that year.

If we made the same calculation for the other large German towns : Hamburg, Duisburg, Frankfort, Ludwigshafen, Mannheim and Breslau, we should find that shipping takes from 40 to 60 per cent of the whole traffic.

The waterway traffic is also important at Budapest, forming nearly one quarter of the whole traffic; it includes more particularly half the cereals traffic. The waterway share increased since 1885, as compared with the railway share.

IX. — Part played by the two systems of carriage as regards imports and exports.

Waterways generally play a very important part as regards imports. We are of course only referring to imports by sea, as at inland frontiers the excess of imports or of exports for one of the two nations is counterbalanced by an equal deficit for the other.

This preference of imports for waterways is explained more particularly by the fact that goods arriving by cargo-boat are in an excellent state for economic transhipment to barges. That is a real superiority of the waterways, whose effect is recorded by the Orleans Railway at Bordeaux, by the Midi Railway at Cette, by the French Western Railway at Havre and at Rouen, and by the French State Railway at Cognac.

This advantage is more especially greatly in favour of the waterway in the ports at estuaries, where the cargo-boat can come into the river in order to tranship, direct and in bulk, its cargo into a number of barges which come alongside.

It is more particularly on the Seine that this phenomenon is to be observed in France. The three curves in the diagram below show how the division of the coal, the wine and the corn traffic has varied since 1885.

Figure 6 shows the up coal traffic from the ports of Rouen and Havre and from the stations of Rouen, Havre and Dieppe. The superiority of the waterways is evident. On the other hand, we have seen that in the northern districts where however there are ample waterways, more than two thirds of the coal traffic was by rail, no doubt owing to the greater facility of loading up trucks which can go to all parts of the coal-pit. We also mention, in the case of imported-coal traffic, a remarkable instance of a rather frequent case, that of competition between a waterway and a railway not parallel to it, competing for traffic which can arrive by sea at different ports : that is the port of Dieppe which formely received and handed over to the railway the traffic which now goes via Rouen and the Seine.

In the case of cereals (fig. 7), the waterways also take an important part of the traffic. It is to be noted that the share of the railway is generally greater in the case of traffic leaving Havre, and that of the waterway in that of traffic leaving Rouen, although the difference between the rates of the methods of conveyance is the same (about 1 franc [9·75*d*. per English ton]), from Havre to Paris and from Rouen to Paris. This confirms the special aptitude of river ports in enabling the transhipment of goods in bulk to be effected under good conditions. The total quantity of cereals imported at Rouen and Havre has however materially diminished owing to the growth in home production; it fell in fact from 1 million tons in 1891 to 400,000 tons in 1906.

Finally figure 8 shows the absolute preponderance of the waterway in case of wine imported by the Seine. We do not give the figures for Rouen and Havre separately, as they are unimportant in the latter case. The important variations found are due to inequalities in the harvests.

Fig. 6. — **Coal sent from Havre, Rouen and Dieppe.**

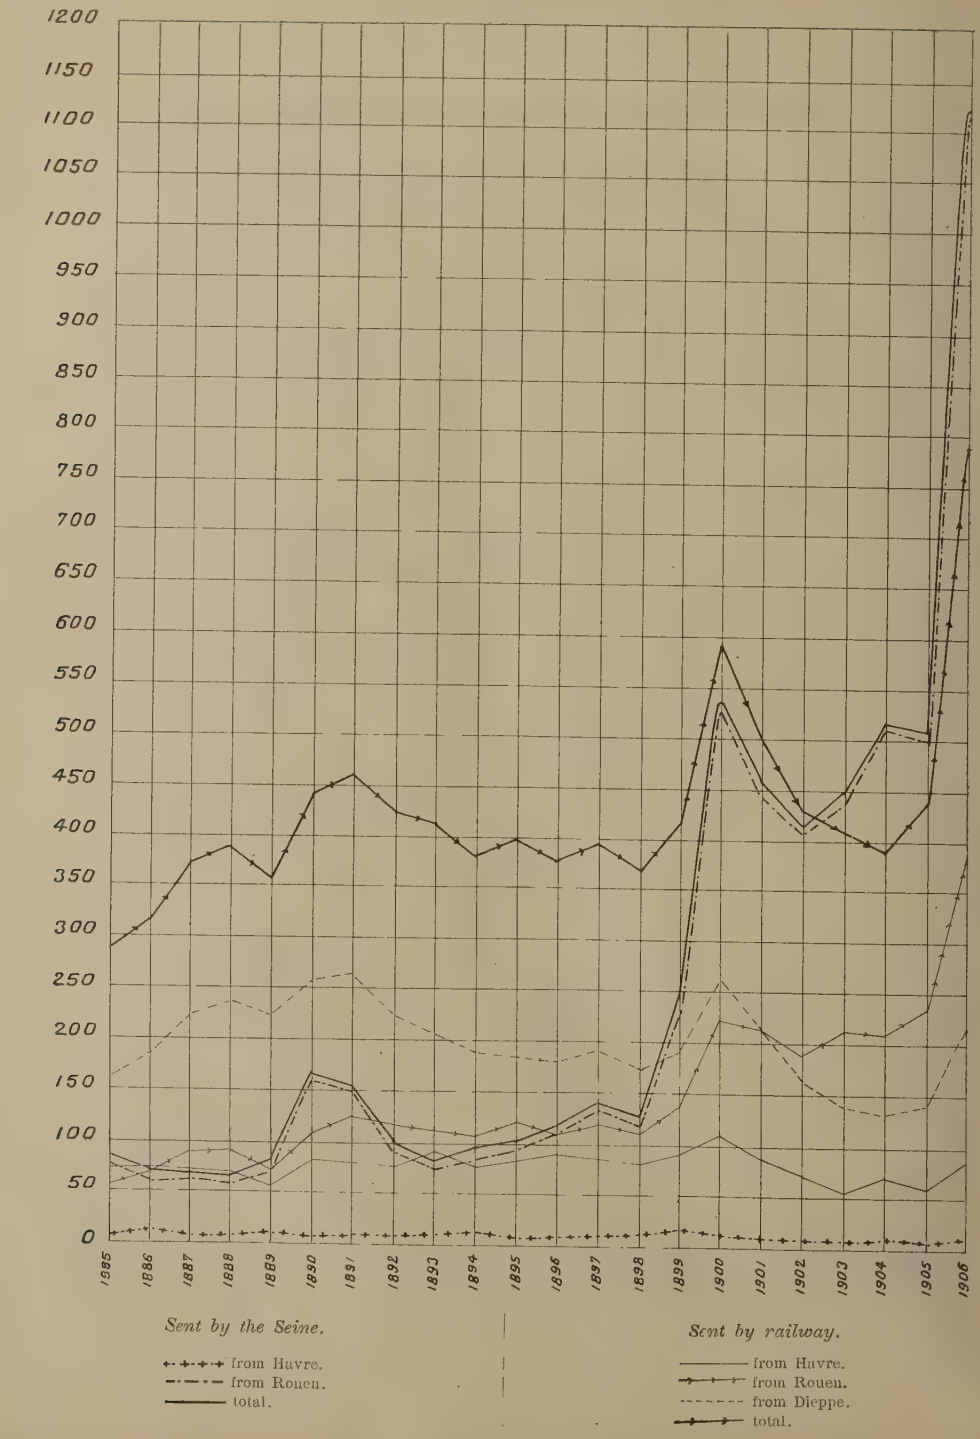


Fig. 7. — Cereals sent from Havre and Rouen.

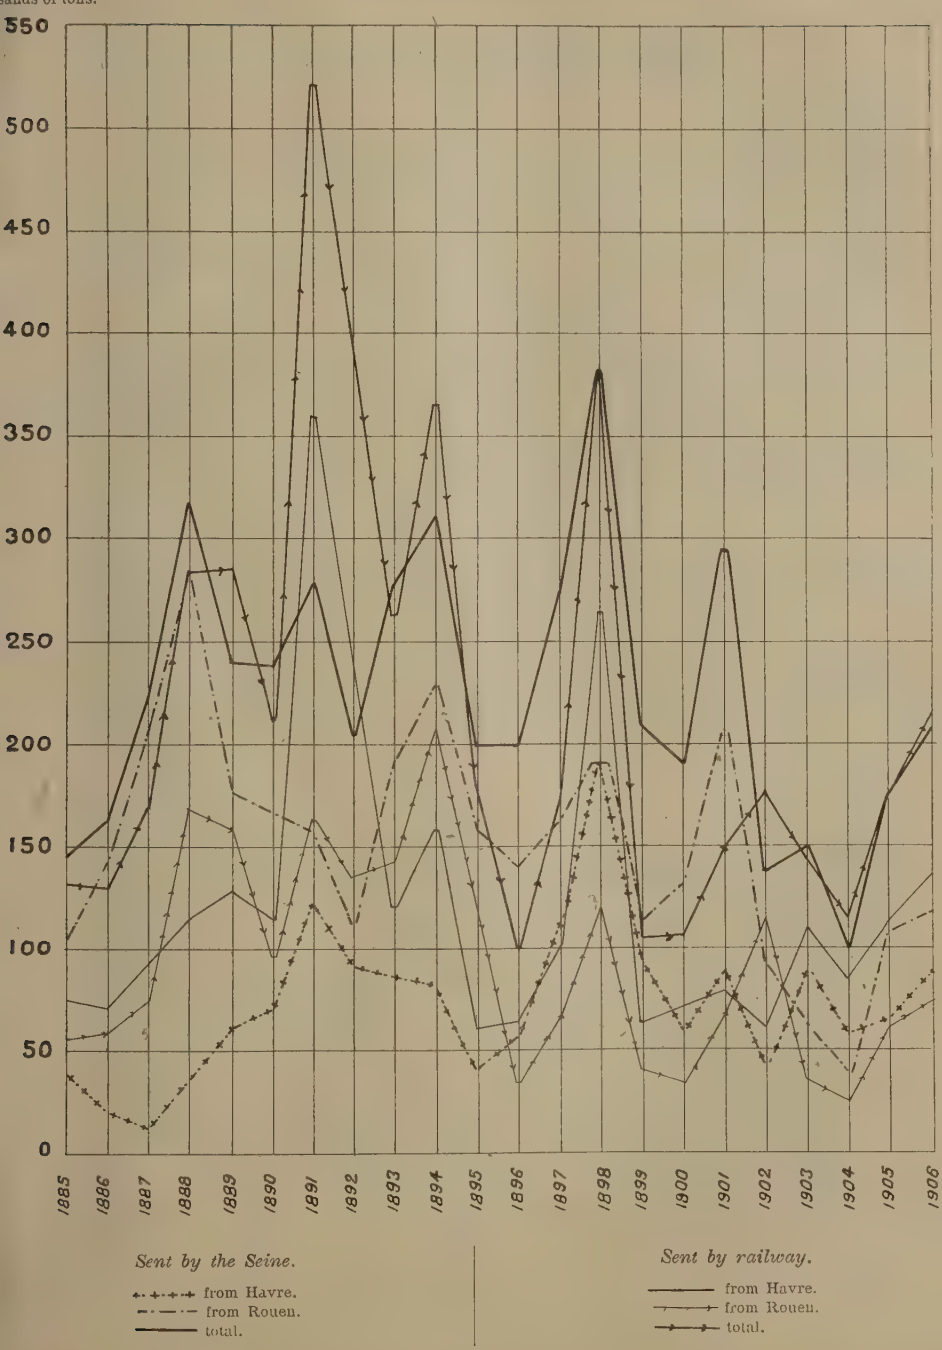

Fig. 8. — **Wine sent from Havre and Rouen.**

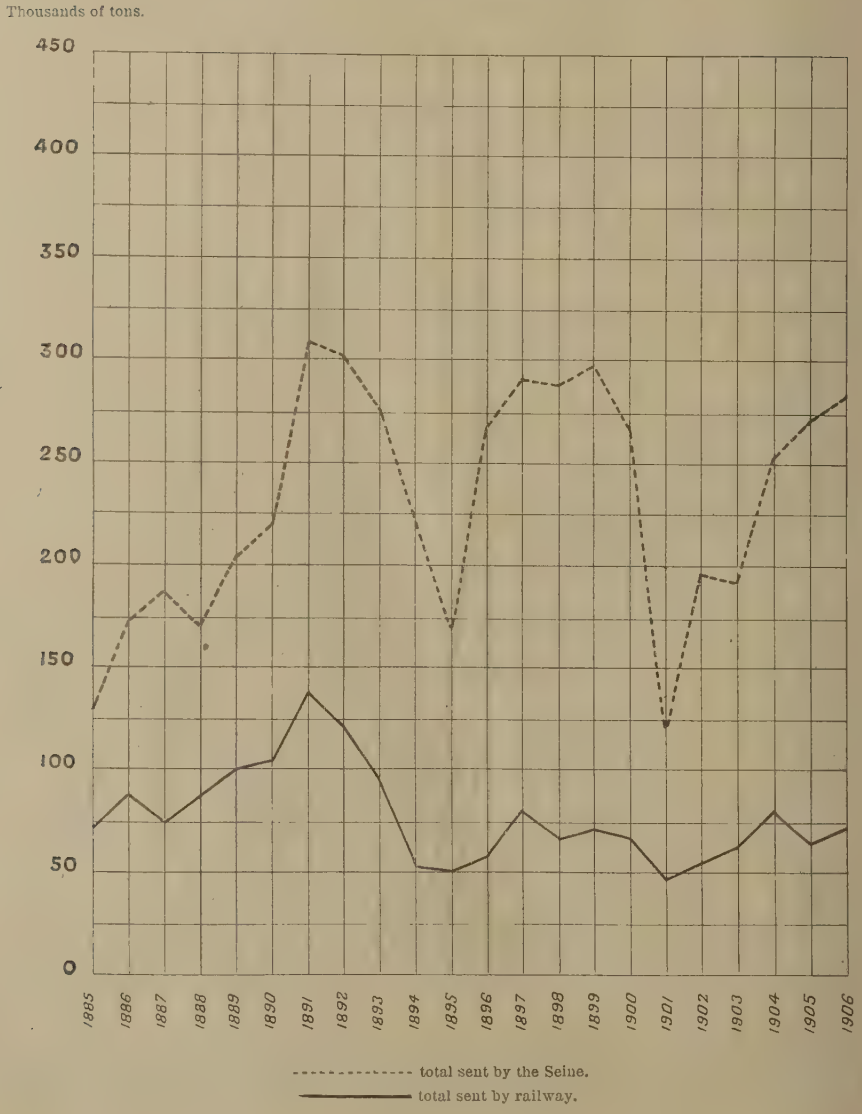


The same preponderance of the Seine shows itself, more and more markedly, in the case of imported foreign timber, as the following table shows :

	1885. Tons.	1906. Tons.
Timber dispatched from Dieppe station.	70,000	23,000
— — — Havre station	70,000	61,000
— — — Rouen station	8,000	59,000
Total sent by rail. . .	148,000	143,000
Timber sent by boat from Havre	2,000	20,000
— — — Rouen	22,000	180,000
Total sent by water. . .	24,000	200,000

We find similar results in Germany. Taking it altogether, the waterways in 1875 imported 3,800,000 tons as against 2,600,000 tons exported; and in 1905, they imported 20,000,000 tons as against 10,600,000 tons exported.

On the Rhine, at the Dutch frontier, in spite of the considerable export traffic in Ruhr coal (4 million tons), the tonnage of imports is 13 million tons, as against exports of 8 million tons (1905).

On the lower Elbe, we find 4,800,000 tons imported as against 3,200,000 tons exported. On the Dortmund canal at Ems, we find 500,000 tons of arrivals as against 250,000 tons of dispatches, and on the Oder 2 million tons as against 900,000 tons.

It is not remarkable that the imports exceed the exports, as Germany is an importing country. But the preponderance of imports is much greater in the case of waterways than in that of railways. The following table for 1900 (in millions of quintals) referring to the port of Hamburg shows this :

	By water.	*By rail.*
Imports	34	13
Exports	26	23

The same observation could be made as regards arrivals of coal and lignite at Berlin, as the following table referring to the year 1905 shows :

		By rail. Tons.	*By water.* Tons.
Coal and coke.	England	131,000	703,000
	Westphalia	160,000	137,000
	Saxony	46,000	...
	Upper Silesia	1,040,000	836,000
	Lower Silesia	320,000	70,000
	Total	1,697,000	1,747,000
Lignite.	Bohemia	23,000	16,000
	Prussia and Saxony.	1,619,000	7,000
	Total	1,642,000	23,000
	General total . . .	3,339,000	1,770,000

We here see that it is the imported English coal which takes most readily to the waterways, which the home coal from Silesia and the lignite from Saxony can however readily use.

But it is above all in the case of imported cereals that the German waterways have acquired a sort of monopoly. This largely depends on the economic transhipment of the cereals in bulk at the river ports. Mr. Peters states that at Hamburg, the cost of transhipment from cargo-boat to wagon is by itself as great as the carriage by water, all handling included, right up to Berlin. On the other hand the protectionist policy opposes any reduction in the tariffs applied to cereals when they are imported. Here are some instances of the different costs of carriage of a ton (per English ton) of corn :

	By rail.	*By water.*
From Rotterdam to Mannheim	23·00 francs (18*s.* 8·3*d.*)	3·00 francs (2*s.* 5·3*d.*)
From Rotterdam to Duisburg	9·30 — (7*s.* 6·7*d.*)	2·50 — (2*s.* 0·4*d.*)
From Hambourg to Magdeburg	15·50 — (12*s.* 7·2*d.*)	4·00 — (3*s.* 3*d.*)

Under these conditions it is intelligible that of the cereals imported into the Rhine basin in 1906, only 100,000 tons came by rail while 3 million tons came by water.

It is natural that the facilities of transhipment from sea-boat to river-boat should have more effect in the case of imports than of exports, because imported goods arrive in large quantities and can be at once reforwarded to the large inland centres, while the exported goods, starting from the points of production, in smaller lots, must gradually be gathered together to form the cargo of a sea-boat. Coal starting from neighbouring coal-pits forms nearly the only exception to this rule.

In spite of these less favourable conditions, the railways might attempt to retain the traffic by reducing their rates, both in the import and in the export direction. But here an obstacle arises which is of considerable importance : the influence exercised by the public authorities, influenced by protectionist tendencies, on the railway tariffs; either the State fixes these tariffs direct on the lines it operates itself, or else it controls them as in France in the case of lines for which concessions have been granted, or finally it intervenes by legal provisions as in certain countries. Public opinion and public authorities are everywhere clamouring for reduced export rates on railways, while always opposing reductions in import rates, even if the sole object of that reduction is to bring back part of the traffic to the railway, by offering advantages similar to those found on waterways.

The impossibility of influencing the traffic on the latter by differences of rate according to direction, and also the exceptional facilities they offer to the importation of agricultural produce, while the home farming, dispersed over the whole surface of the country, profits but little from the construction of canals which are only useful to a very limited part of that surface, explain the hostility of protectionists and farmers against waterways in many countries, particularly in Germany.

It is more difficult to understand the attitude of the protectionists who in some countries, particularly in France, recommend the construction of waterways, while energetically protesting against the least reduction in the rates by the railways, to enable the latter to retain the traffic the waterways take away from them.

X. — Disturbance in the equilibrium between the two systems of carriage.

All the different factors we have been considering tend to produce a state of equilibrium, a normal division of the traffic between the two systems of carriage; but that state of equilibrium is frequently disturbed.

Certain causes of trouble are connected with the policy adopted by the administrations which operate the railways or control them; these we will consider in chapters XI and XII. We will here only consider causes independent of all human will; there are three principal ones:

1° The stoppage of the waterways;

2° The variations in economic activity in accordance with the season of the year;

3° The long-period variations in that activity, that is to say the periods of industrial booms and the slumps which succeed them.

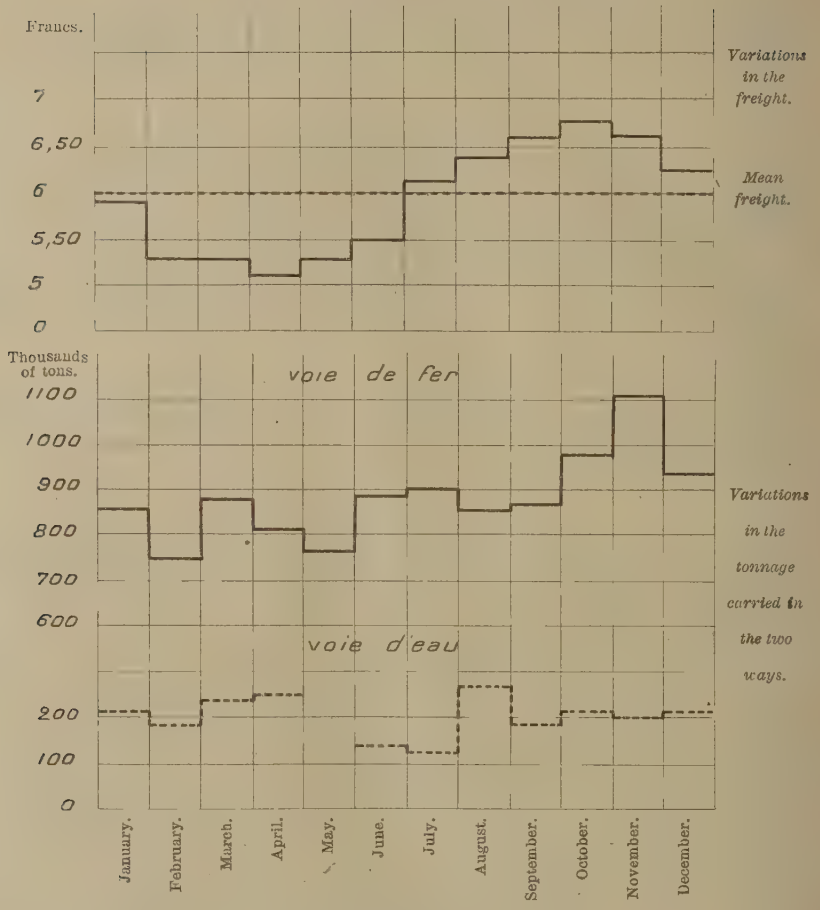
1° Part of the stoppages is due to frost. The duration of these interruptions varies in different climates, but it is generally foreseen by the consignors who make arrangements to send their consignments in good time. Thus they produce but little variation in the division of the traffic, except in years when they are of abnormal length.

The canals are sometimes stopped for the execution of works; this becomes rarer and is generally known in advance with complete exactitude.

River traffic on the other hand is liable to partial or total stoppage, for periods which are more irregular as to date and as to duration, owing to low water. Such stoppages last sometimes for many months, for instance on the upper part of the Rhine, the Elbe and the Oder. On the Rhine and the Elbe, the economy effected by using the waterway is sufficiently great that of the goods which generally go by water, only those of high value and urgently required go by rail when the river cannot be used, instead of waiting for a more favourable season.

Taking the general case, the stoppage brings the railway an extra amount of traffic; but this is not always an advantage to the railway, when that extra amount comes at a time when its own proper traffic is exceptionnally brisk, as quite frequently happens. This disadvantage is mentioned in France by the French Eastern and the French Northern railways, who state that the stoppage due to ice is generally coincident with the time of the heavy traffic in coal and beetroot. The Austrian and Hungarian railways also mention that the stoppages on the Elbe, the Danube (three months) and its tributaries the Tisza (four months), the Drave and the Save (five months), occur in autumn, just when the railway has most to do.

Fig. 9. — **Carriage of coal from Lens to Paris in 1898.**



Explanation of French terms: Voie de fer = Railway. — Voie d'eau = Waterway.

2° During the course of one and the same year, the activity of the traffic varies according to time and season. But the traffic-capacity of the boats remains the same; owing to the slowness of their progress, they cannot make a greater number of voyages. The waterway practically cannot take any of the extra tonnage offered; the sole effect of the increase in the demand is to make freight go up, and this difference displaces the point of division between the two ways, by sending the excess the waterway cannot take, to the railway, which is compelled to carry all traffic

which turns up, at its usual rates and inside the regulation time. The diagrams above (fig. 9), drawn by the French Northern Railway for the year 1898 (a normal year), show that in autumn the freight for coal rises; but it is the railway which carries the extra tonnage.

3° A similar phenomenon is produced, marked by oscillations of greater amplitude, owing to the variations in the economic activity from one year to the other. We now observe in all countries periodic industrial and commercial crises, which recur at rather long intervals and immediately react on the activity of traffic. Is this reaction the same on waterways as on railways? We must distinguish between two periods : the boom and the slump.

a) During boom times, shipping hardly increases its normal rate of development of stock and of staff, for any material increase cannot be produced quickly. On the other hand, the amount of work done by the existing stock increases but little; shipowners generally content themselves with profiting by the rise in the rates, which naturally results from the increased demand in presence of a stationary supply, and this rise is only limited by the tariff of the railway.

Then also during boom times the increase of traffic is not appreciably greater than the average increase; matters are quite different with the railway, which is compelled to carry all the additional traffic, even at ruinous expense. It must be added that during industrial booms, the public attaches much more importance to speed, and this also tends to increase the share of the railway. In 1907 a certain number of manufacturers in the east of France went so far as to have metals carried as quick freight.

The phenomenon we are describing may be understood by following the development of traffic on the French railways and waterways during the last thirty years.

DEVELOPMENT OF TRAFFIC.	Slow-freight traffic, in millions of ton-kilometres (in millions of English ton-miles).		
	Railway.	Inland waterway.	Total.
Traffic in 1878	8,400 (5,140)	2,005 (1,326)	10,405 (6,363)
Traffic in 1907	19,890 (12,160)	5,370 (3,280)	25,260 (15,440)
Increase	11,490 (7,030)	3,365 (2,058)	14,855 (9,088)
Total increase, per cent.	137	168	143
Mean annual increase per cent *per year* . .	4·4	5·5	4·6

Taking it altogether, the mean increase of the inland waterway traffic has been slightly greater than that of the railway traffic. Now during these thirty years, the traffic industry has passed through four periods of exceptionally rapid progress :

1878-1883, 1886-1890, 1897-1900 and 1904-1907. We give for each of these periods a table similar to the preceding table :

PERIOD OF BOOM.		Slow-freight traffic (in millions of ton-kilometres [in millions of English ton-miles]).		
		Railways.	Inland waterways.	Total.
1878		8,400 (5,137)	2,005 (1,226)	10,405 (6,363)
1883		11,065 (6,767)	2,383 (1,457)	13,448 (8,224)
Increase from 1878 to 1883	total	2,665 (1,630)	378 (231)	3,043 (1,861)
	per cent.	31	19	29
1886		9,314 (5,696)	2,798 (1,711)	12,112 (7,407)
1890		11,759 (7,191)	3,216 (1,967)	14,975 (9,158)
Increase from 1886 to 1890	total	2,445 (1,495)	418 (256)	2,863 (1,751)
	per cent.	26	15	24
1897		13,791 (8,434)	4,365 (2,669)	18,156 (11,103)
1900		16,557 (10,126)	4,675 (2,859)	21,232 (12,985)
Increase from 1897 to 1900	total	2,766 (1,692)	310 (190)	3,076 (1,882)
	per cent.	20	7	17
1904		16,551 (10,122)	4,968 (3,038)	21,519 (13,160)
1907		19,890 (12,160)	5,371 (3,285)	25,261 (15,445)
Increase from 1904 to 1907	total	3,339 (2,042)	403 (246)	3,742 (2,288)
	per cent.	20	8	17

Thus we find that although lately it has progressed more slowly, the railway traffic has shown much greater increase than waterway traffic at boom times.

It may hence be asserted with absolute certainty that waterways do not take their proportional share when a boom results in a sudden increase of traffic, and that the railway carries nearly all the resulting additional traffic, not only that sent by its own customers but also that sent by the customers of the waterways. It is far from complaining about this, as long as this additional traffic is not too great; as long as the surplus is somewhere near the normal (4·5 per cent per year in France), the railway must be equipped so as to be able to cope with it; it can even meet slightly greater increases, by a more perfect utilization of its stock and by working more briskly. But beyond a certain limit, any sudden increase in the traffic becomes very troublesome.

In particular, during the last boom (1904-1907), the increase on the railway during these three years amounted to 17·4 per cent, a figure not much exceeding the normal ($3 \times 4{\cdot}5 = 13{\cdot}5$ per cent), if the surplus had been divided like the normal increases. As the waterways only took half of their share of the increase (8 per cent), all the surplus came on to the railways. Its total increase thus came

to 20·1 per cent, and a very expensive effort was necessary to meet it, without however escaping the complaints of the public, which does not grasp the situation and often attributes the deficiences of the service only to those of the ways which alone strive to meet the exceptional needs from which the others shrink.

b) It would seem that the inverse phenomenon should be produced during times of slump, shipping being able to lower its rates in order to avoid standing idle, and thus being able to obtain a proportionately greater share of the total traffic.

The traffic industry in France has had two notable times of slump during the period which we are considering. Let us draw up for them a table similar to the last :

PERIOD OF SLUMP.		Slow-freight traffic (in millions of ton-kilometres [in millions of English ton-miles]).		
		Railways.	Inland waterways.	Total traffic.
1883		11,065 (6,767)	2,383 (1,457)	13,448 (8,224)
1886		9,314 (5,696)	2,798 (1,711)	12,112 (7,407)
Increase from 1883 to 1886	total	—1,751(—1,071)	415 (254)	— 1,336 (— 817)
	per cent.	— 16	17	— 10
1900		16,557 (10,126)	4,675 (2,859)	21,232 (12,985)
1902		16,172 (9,890)	4,465 (2,731)	20,637 (12,621)
Increase from 1900 to 1902	total	— 385 (— 235)	— 210 (— 128)	— 595 (—363)
	per cent.	— 2	— 4	— 3

During the first slump, the most serious the railway business has ever known, the railway traffic decreased by 16 per cent, while on the other hand the waterway traffic continued to increase at its normal rate : 17 per cent in three years. It must not be forgotten that that period of slump was precisely coincident with the time during which shipping first benefited by the deepening of the Seine, by the unification of the type of canal resulting from the adoption of the Freycinet plan, and finally by the abolition of tolls, which was decided on in 1880; it was thus natural that it should take an increasing share of the total traffic. But it should be noted that it progressed owing to the advantages bestowed by the public authorities, not owing to the needs of commerce, which were diminishing.

During the 1900-1902 slump, on the contrary, each of the two ways shows a loss at the end of the three years. This loss is but small, but waterways show twice that of railways. It is true that a special cause, the end of the building work carried out on the Seine for the Exhibition, and of its subsequent demolition, resulted at that time in the disappearance of an exceptionally large quantity of traffic.

Thus taking it altogether, it is not evident that during slump times waterways always and necessarily suffer less than railways. A plausible explanation of this can be given. Crises affect above all the large traffic, which gives waterways their

*

chief work, and have less influence on the exchange of articles of food and of current consumption, of which railways always carry the chief share. Retail commerce, which only uses the railways, is affected less, or more slowly, by the slump than the wholesale trade, which utilizes the waterways. The normal development of the traffic carried on the railway can thus compensate it, in part at least, and as long as the slump remains moderate, for the reduction in the traffic of the wholesale manufacturers and traders, even if it feels it as much as the waterways, or even more.

XI. — Measures taken by the railways to fight the competition of waterways.

The railway can try to retain, by means of special tariffs, the traffic which the waterway is trying to take away from it. The rates of the latter (except in the case of certain regular services catering for traffic of a special nature and carried by one company or by several companies who have come to an understanding) are chiefly determined by the competition between shipowners. They approximately represent the net cost of the carriage proper, increased in some cases by a slight toll, which as a rule hardly covers the cost of upkeep of the ways. The railway rates, on the other hand, are monopoly rates; to the sum necessary for covering the cost of the carriage proper, there is added an amount, varying with what each consignment can pay, and often rather large, intended to contribute towards the remuneration of the capital expended on the railway. By reducing that part of the rate, the railway can retain traffic it would otherwise lose and thus keep part of the net profit this traffic would yield and which it needs to meet the financial charges weighing on it.

The competition of the railways can thus be direct, when it is for traffic which the waterway can carry from terminal to terminal, or indirect, when it tends to prevent or restrain mixed carriage by measures taken on the railway lines which would form continuations of the waterways.

We will illustrate, by a certain number of examples, the influence which such competition measures have had on the division of the traffic.

A. — *Direct competition.*

Direct competition is the most usual measure adopted by railways, when it is possible. For this purpose it is necessary that freights should not be too low, and moreover, that the railway should be able to reduce its rates sufficiently.

This procedure was formerly very usual in France. We have in fact seen that except on the Seine freight hardly ever falls, in the main directions of the traffic, to below from 1·2 to 1·5 centimes per ton-kilometre (0·188*d*. to 0·235*d*. per English ton-mile). Taking into account the longer distances and the other disadvantages

of the waterways, this freight can hardly compete against a rate of 2 centimes per ton-kilometre (0·314*d*. per English ton-mile) which, as we shall see later on, still leaves a small profit for the railway in case of most of the traffic for which the waterways compete.

The French railways have been restrained, in their reductions of competing rates, by the rules in connection with the authorization of the tariffs. This authorization is given by the Minister of Public Works, on the advice of the consultative railway committee.

For a long time now, according to the doctrine of that committee, a rate for competing with the waterways is not authorized unless it is 20 per cent higher than the corresponding freight. It must be added that the administration no longer admits, except exceptionally, reductions of rates in the form of fixed rates, applying to certain relations only; but generally demands a generalization, in the shape of a scale, applying to the whole system. This would nearly always make the railway lose more in connexion with the traffic it carries in any case, than it could gain from the traffic competed for. Finally, the railway is prevented from trying reductions, the result of which would be doubtful, or for meeting temporary needs, by the practical impossibility of raising its rates again; there has hardly even been an instance a rise of being authorized. The result of this situation in France is that rates which are really competition rates are no longer made. A certain number of reduced rates are however in existence, made formerly with a view to competition. On the other hand, among the new rates authorized, either for general purposes, or in order to extend to an industrial centre, the advantages previously granted to other places, there are occasionally some of a nature to modify the division of important currents of traffic between competing railways and waterways.

We will mention in this connection, as having led to an appreciable increase in the share of the railways, the modification in the coal rates introduced in July 1903 by the common Eastern-Northern tariff No. 107, which gave the results shown in the following table :

Arrivals on the Eastern system.

YEAR.	TOTAL.	BY RAIL.		BY WATER.	
	Tons.	Tons.	Per cent.	Tons.	Per cent.
1901	2,322,000	1,743,000	75	579,000	25
1902	2,283,000	1,726,000	75·6	557,000	24·4
1903	2,736,000	2,052,000	75	684,000	25
1904	2,847,000	2,194,000	77	653,000	23
1905	2,379,000	2,676,000	79·1	703,000	20·9

Similarly we may mention, as regards combined rates, a fixed rate from Rosières, which is in force since 20 April 1898, and which has given the following results :

Traffic to Paris.

YEAR.	TOTAL.	BY RAIL.		BY WATER.	
	Tons.	Tons.	Per cent.	Tons.	Per cent.
1895	26,800	4,800	17·9	22,000	82·1
1896	29,400	3,500	11·9	25,900	88·1
1897	27,400	4,900	17·8	22,500	82·2
1898	31,600	8,800	27·8	22,800	72·2
1899	37,900	15,900	41·9	22,000	58·1

We have stated that railways have above all to fear waterways as regards long-distance traffic. It will accordingly be noted that competition rates are often common rates.

In certain cases, although the effect of certain tariffs has been appreciable it is impossible to prove this by figures, because this effect has been, not to make the railway obtain more traffic, but to consolidate an acquired position; the reduction has only followed the progressive reduction of the freight or met an attempt of a shipping company to take away traffic.

We must look upon the successive reductions in the rates for coal carried from the north to Paris, made by the French Northern Railway, in this light. The progress in the operation of railways has made it possible to realize reductions corresponding nearly to those which the improvement in waterways made in the freights, and the division of the traffic between the two ways has not been materially affected. The share of the railway, which amounted in 1886 to 880,000 tons as against 797,000 tons carried by water, amounted in 1905 to 1,950,000 tons as against 1,620,000 tons carried by water.

We may also mention the reductions in the rates granted to wines in 1894 by the Midi Railway. The reductions made after the replanting of the vineyards which had been destroyed by the phylloxera, in order to enable the wines produced in the south of France to compete in the Paris market, which had during the time of that scourge been entirely captured by Spanish and Italian wines coming by way of Rouen and the Seine, have had the effect of stopping a movement which was beginning to attract to the same way the wines produced in the districts round Cette and Bordeaux, and even to concentrate on these ports, by the Midi canal and the lateral canal of the Garonne, those of the intermediate region.

The fixed rates recently applied to American cotton sent from Channel ports to

the Vosges, have been but an answer to offers made to the spinners by the Havre-Paris-Lyons-Marseilles Company, in order to take the traffic away from the railway.

The most striking instance perhaps is to be found in the considerable reductions the Midi Railway made in the rates on the Bordeaux-Cette line, at the moment when the Midi canal was repurchased in 1898. In order to abolish tolls on the whole of the waterway from Bordeaux to Cette, the government also wanted to repurchase the lateral canal of the Garonne, for which the railway held the concession. This repurchase could not be effected except by agreement with the railway, except indeed in the case of repurchase of the whole system of the latter. The railway only agreed subject to the authorization of a special very reduced tariff, for the most important goods, on its trunk line, which runs alongside the canal the whole way and which would have lost nearly the whole of its traffic if the tolls had been abolished on the canal and the railway had not modified its rates. This reduced tariff, which applies to wine, cereals, sugar, timber, fodder, cement, etc., in truck-loads of at least 5 tons, gives a total rate of 4·50 francs for 100 kilometres (3*s.* 7·5*d.* for 62 miles) and one of 9·75 francs for 400 kilometres (7*s.* 10*d.* for 248 miles, all extra charges included. It has attained its object, for the railway has retained nearly the whole traffic, and that on the canal has hardly increased, in spite of the abolition of the tolls which amounted to several centimes per kilometre. But the Midi Railway estimated the loss of receipts resulting from this reduction at 5 or 6 millions francs (£200,000 to £240,000) per year, at the time the reduction was made; the actual loss, calculated on a rapidly-growing traffic, would be much greater.

Besides these cases, where the share of the railway has been increased or retained as a result of modifications in the tariff, we must mention that of the French Western Railway, which has been ruined by the competition of the Seine, which has taken away all the traffic on its best line, that from Paris to Havre.

It was about 1878 that the work of deepening the water channel between Rouen and Paris to 3 metres (10 feet) was completed. We will not examine whether the reductions to which the railway would have had to agree in order to retain its share of the traffic, would not have been ruinous; that is possible, but not certain, for it would have had to fight against a way technically much superior to the Midi canal, but so tortuous that distances are nearly doubled. But the railway did not, as in the case of the Midi, have rights over part of the waterway, enabling it to make conditions. In order to compete, it would have been necessary to obtain the authorization for very reduced tariffs applying to imported goods, corn, wine, timber, coal (via Dieppe), etc. Protectionist opinion, which never raised any objection to the improvement of the Seine, opposed all attempts to reduce the tariffs which were the consequence of this. After having with difficulty obtained the authorization for some reductions, too small to be effective, the railway had to give up proposing any others and the triumph of the Seine shipping was complete. This can be well

recognized if we compare the traffic, in the two directions together, on the sections where the current of the disputed traffic is not mixed up with any other, namely : 1° on the Seine between Rouen and the the Oise junction ; 2° on the Mantes-Rouen section of the Paris-Havre line.

YEAR.	Mean traffic per kilometre (0 62 mile) (in tons).	
	Seine (from the Oise to Rouen).	Railway (slow-freight) (from Mantes to Rouen).
1881	678,000	1,547,000
1905	2,019,000	1,448,000
1906	2,653,000	1,782,000

It must also be added that the railway benefited in 1906 by an increase in the traffic which is probably not lasting, owing to the want of sufficient shipping to carry the enormous quantity of English coal imported viâ Havre and Rouen after the Courrières accident. If this flow becomes permanent, as seems probable, it is not to be doubted that shipping will in time take all of it.

As regards the tonnage of the consignments forwarded from the two great ports at the ends of the Seine, we have mentioned in chapter IX above (figs. 6, 7 and 8) the results attained by different goods. The annexed diagram fig. 10) gives a summary of the whole state of the up-river traffic, year by year.

Tariffs of direct competition aimed at the waterways are common abroad. We have unfortunately only been able to collect rather limited information as to their peculiarities and as to the results obtained.

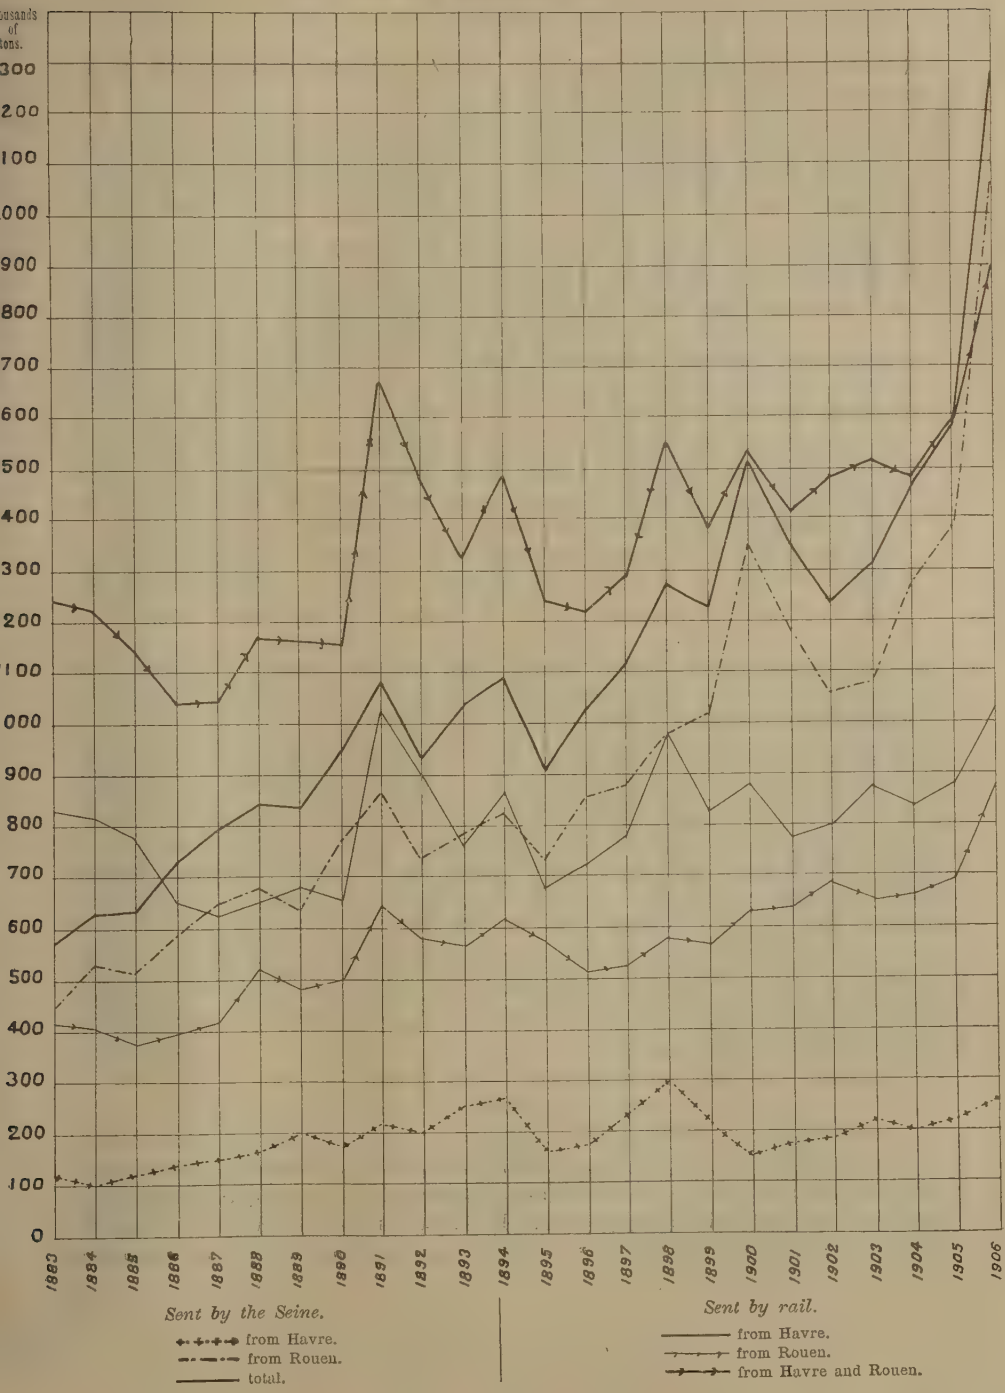
The Austrian State Railway and the Hungarian State Railway inform us of the existence of many reductions in the tariffs caused by the competition of the Danube shipping.

There are in Russia a certain number of competing tariffs, the most important being those which have the object of diverting from the waterways the traffic in soft goods from Moscow to Astrakhan, in candles from Kazan to Moscow, in corn from Astrakhan to Moscow or from the Donetz to the Crimea.

We may state generally that there are two species of competing tariffs which are particularly effective against waterways :

1° In the first place we must mention the tariffs which only apply to large consignors, the best customers of the waterways, without including any corresponding sacrifices in favour of other traders. The Dutch State Railway adopts this system, by making special contracts with the large consignors. The Belgian State Railway

Fig. 10. — Total traffic from Havre and Rouen from 1883 to 1906.



adopts the same system, by applying article 3 of the Royal order of 28 December 1891; we think it of interest to give its text below :

Art. 3. — Exceptional reductions in the rates of the tariffs are granted under the following conditions to all who demand this of Our Ministry of railways, post and telegraphs :

1° That it is proved that at ordinary rates of the tariffs the conveyance would not be effected by rail;

2° That the party benefiting by the reduction accepts conditions of carriage which will make it possible to realize a saving in the working expenses, notably :

a) The regular supply, for carriage, of consignments each of sufficient size to form a complete train-load of at least 150 tons; *b*) the dispatching, on days fixed in advance, of at least one train per week during a minimum period of three months;

3° That the reduction does not have the effect of modifying the conditions of competition between natives of the country.

The maximum amount of the reduction is equal to the difference existing between the rate of the tariff and the cost of the carriage if effected in any other way.

An order of our Minister of railways, post and telegraphs will record that the above conditions are complied with and will fix the amount of the reduction.

In the case of traffic carried under these conditions, the compenation to be paid eventually in the case of loss or damage, such as determined in article 26 of the home tariff of the State, shall be reduced one half

The French railways obtain a simular result, but less complete, by the development of their tariffs applying " from private siding to private siding " in the case of consignments in wagons of 40 tons belonging to the consignors.

2° Another method adopted by certain railways in order to reduce to a strict minimum the loss of receipts resulting from reductions in the rates made necessary by competition, is to suspend their applicatipn during the period when navigation is stopped. Thus during this period the reduced rates of the Hungarian State Railway are raised 10 per cent. This is also done in Russia in the case of many tariffs; for instance the rate for candles from Kazan to Moscow (1,042 kilometres [647 miles]) is 72·82 francs per ton (£2.19*s*. 2·3*d*. per English ton) from 15 October to 15 April and 41·05 francs per ton (£1.13*s*. 4·4*d*. per English ton) from 15 April to 15 October. Similarly certain reduced tariffs are not granted by the Austrian railways except to consignors who guarantee them a certain tonnage while navigation is open.

B. — *Indirect competition.*

On certain rivers, freights are so low that competition is impossible or ruinous for the railway if the conveyance begins and ends on the waterway. This happens on the Volga, the Rhine and the Elbe. But there is always competition possible in the case of *mixed traffic*, that is to say in case the waterway is used for part of

the journey between two points which are not immediately adjoining the waterways.

In that case, the natural policy of the competing railway is to reduce to a minimum the section along the river for which mixed carriage is cheaper than direct railway carriage. It can proceed in two different ways : 1° make a reduced through rate, so as to take the traffic between points the least near to the waterway, and lead to the substitution of railway carriage pure and simple for the mixed carriage; 2° as regards traffic which it is impossible to attract wholly to the railway, combine the rates in such a way as to make the traffic pass from the waterway to the railway at a point such that the rail journey is a maximum.

In France, mixed traffic is rare, although the railways have hardly done anything to avoid it. Freight seldom falls very low, there are but few transhipports, not well situated and not well equipped. All the railways had to do in order not to develop this kind of traffic was not to establish such ports; and they had no obligation to connect their systems with the new transhipports that the State might have established. A recent act (3 December 1908) has just imposed this obligation on them, granting them as compensation a right of indemnity as regards charges and loss of receipts they would incur; under these conditions it is not to be expected that this act will receive many applications.

As against existing transhipports, the railways formerly adopted the making of fixed rates by which the traffic which went wholly by rail benefited, but which were not applicable to mixed traffic. Even when they cannot adopt this procedure, the rapid decrease of the bases of the kilometre rates suffices, in most cases, to make mixed carriage less advantageous than through railway carriage. The development of reduced common tariffs, common to several railways, vigorously demanded by the public in the general interest of long-distance traffic, has naturally had the effect of reducing the use of mixed carriage. We may mention, from this point of view, tariff 114 (west-north-east) for metallurgical produce and tariff 102 (common to all the railway systems) for grains and cereals. The latter, in particular, has brought back wholly to the rails 40,000 tons of barley formerly sent from Beauce to the north by rail to Ivry and thence by boat.

In Russia, direct competition, of which we have already given some instances, is rather rare. It cannot be brought to bear against the Volga, as there are no railway lines along it and as freight is very low there, but only against the waterways of the second order, the lower Dnieper in which there are rapids, the Moskova, and above all the Marie system between the Volga and St. Petersburg. Indirect competition is however much practised under the second form we have mentioned and which consists in keeping the mixed traffic as long as possible on the railway.

If for instance we take the traffic going up the Volga, a reduced tariff will be made in order to divert it as from Kazan or Nijni-Novgorod, if it is going to Moscow, or as from Rybinsk, if it is going to St. Peterburg, and vice versa. We give in a table below the more important tariffs known as " navigation tariffs ". It will be

noted that most of these tariffs, which show reductions of from 20 to 50 per cent as compared with the normal tariffs, are not applicable during the periods when navigation is stopped.

CLASS OF GOODS.	Sent		Distance in kilometres (in miles).	Period of application of reduced tariff.	Rate in francs, per ton (per English ton)	
	from	to			normal.	reduced.
Tallow	Rybinsk.	St. Petersburg.	618 (384)	15 April-15 Nov.	38·09 (£1.10*s.* 11·53*d.*)	14 44 (£0·11*s.* 8·84*d.*)
Canvas	Rybinsk.	St. Petersburg.	618 (384)	15 April-15 Oct.	88·55 (£3.11*s.* 11·72*d.*)	44·10 (£1.15*s.* 10·15*d.*)
Molasses	Rybinsk.	St. Petersburg.	618 (384)	15 April-15 Oct.	33·89 (£1.7*s.* 6·56*d.*)	17·66 (£0.14*s.* 4·26*d.*)
Leather and hides . .	Kazan.	Moscow.	1,042 (647)	15 April-15 Oct.	139·75 (£5.13*s.* 7·13*d.*)	64·00 (£2.12*s.* 0·26*d.*)
Rope and cordage . . .	Rybinsk.	Rostov (Don).	1,598 (993)	15 April-15 Oct.	68·36 (£2.15*s.* 6·79*d.*)	43·42 (£1.15*s.* 3·52*d.*)
Cereals	Rybinsk.	St. Petersburg.	618 (384)	15 March-15 Sept.	24·47 (£0.19*s.* 10·68*d.*)	16·10 (£0.13*s.* 1·01*d.*)
Metallurgical produce .	Rybinsk.	St. Petersburg.	618 (384)	The whole year.	23·54 (£0.19*s.* 1·61*d.*)	14·99 (£0.12*s.* 2·21*d.*)
– – .	Nijni.	St. Petersburg.	1,103 (645)	The whole year.	32·60 (£1.6*s.* 5·98*d.*)	23·04 (£0.18*s.* 8·73*d.*)
– .	Jaroslav.	Moscow.	286 (178)	The whole year.	15·17 (£0.12*s.* 3·97*d.*)	8·45 (£0·6*s.* 10·42*d.*)
Salt	Rybinsk.	St. Petersburg.	618 (384)	The whole year.	22;04 (£0.17*s.* 10·97*d.*)	14·17 (£0·11*s.* 6·22*d.*)
–	Nijni.	Moscow.	427 (265)	The whole year.	17·84 (£0.14*s.* 6·01*d.*)	11·85 (£0.9*s.* 7·59*d.*)

Taking it altogether, the Russian government seems to have followed a very rational policy in not building railways along the first-class river system it possesses, and in trying to attract the traffic to the railways which are connected with these large rivers, as soon as these iron roads make it possible to offer to the public as advantageous a rate for the whole journey, while carrying the traffic as far as possible on their own rails. The railway in fact leaves a certain profit for the remuneration of the capital, after having covered the special costs of the carriage, while all the permanent charges of the waterway fall on the Treasury without direct compensation.

It is in Germany that the mixed traffic has become developed most. It is there that we shall find, apposed to that system of carriage, the most distinct measures of competition and of cooperation. For the moment we will only consider the former. We shall find them in Prussia.

We have already stated how low the freight is on the large German rivers. The

railways cannot attempt any direct competition against them. Indirect competition is on the contrary possible at all the points which do not immediately adjoin rivers, particularly as regards the industrial districts of Westphalia, Bavaria and Silesia. The Prussian railways have hence quite naturally tried to reduce the importance of the mixed traffic, when it is possible to divert it.

The principal method adopted is the establishment of very reduced exceptional tariffs for the seaports. These tariffs are moreover justified by other considerations of national economy; they are intended to favour, according to case, imports or exports, and to support the German seaports as against the foreign ports. But they also have the result, very frequently, of making through carriage by rail more advantageous than mixed carriage which must pay, besides the freight, the insurance and the transhipment, rather high charges for the booking, and a rate for the carriage to the transhipment port, also rather high, for it is calculated on quite another basis than the through rate.

These tariffs have given rise to numerous protests made by the shipowners and a large number of towns which have transhipment ports, such as Mayence, Frankfort, Magdeburg, Breslau. The strongest complaints came from the largest of all these ports, namely from Ruhrort-Duisburg. The latter business town maintains that it also is a seaport, as it makes exchanges with countries beyond the sea by through bills of lading and even by direct navigation; it therefore claims the application of the reduced scales of rates which form the tariffs of seaports, and Magdeburg makes the same claim.

The Prussian railways generally answer with a refusal [1]. We will quote their answer under date of 4 February 1905 to the Chamber of commerce of Magdeburg, on the subject of the reduction of the rates on sugar, and we will reproduce from it a passage which will show the very reasonable doctrine of the Prussian railways on this point:

« ... We have to remind you that modifications in the tariffs, claimed in the interest of the traffic, must not be rejected because they might be injurious to the waterways. Inland navigation, in fixing its freights, has never paid regard to the railway traffic, and the extraordinary progress of inland waterways during the last ten years is largely due to the considerable reduction in the freight, which has attracted to the waterway a considerable portion of the traffic which would otherwise have gone to the railway... There are strong objections to extending in a general way the exceptional tariffs to the transhipment ports. This measure would result in diverting to the waterways part of the railway

---

[1] The Prussian railways have exceptionally received these demands favourably, taking care that the reduced tariffs granted to the transhipment ports are never as advantageous as the seaport tariffs. This is the case with certain reductions (which we will refer to later on) granted to Breslau, and with reduced rates granted to Frankfort and Mayence for the carriage of chalks and slates coming from Thuringia, from Saxony and from Bavaria, and which are going to be exported.

traffic. This would assuredly be injurious to the general interests of commerce, for the traders in the immediate neighbourhood of the waterways would then benefit by new reductions in the tariffs: they would be still more favoured as compared with other traders only served by the railway, who already have to bear heavier charges for their traffic. Injured in their conditions of competition, the latter would suffer the consequence of the loss of a large traffic by the railway, which would thus see vanish the possibility of granting the reductions in the tariffs asked for in the general interest of trade. »

It is interesting to show, by a few figures, what has been the result of the indirect competition against this mixed carriage. On the Rhine, this competition makes itself felt very seriously in the case of exports, particularly as regards coal. This is shown by the following statement which gives, for the two years 1886 and 1906, the amount of coal exported from Westphalia to Holland and to Belgium by rail and by water :

	By rail.	*By water.*
In 1886.	1,834,000 tons.	1,831,000 tons.
In 1906.	5,410,000 —	3,349,000 —
Proportional increase	195 per cent.	82 per cent.

The increase has thus been more than twice as great by rail as by water. This is all the more remarkable as during the same period the amount of Westphalia coal sent up-river increased from 1,743,000 tons to 5,446,000 tons, an increase of 212 per cent.

As regards imports, the share of the Rhine is continually increasing, to the detriment of that of the railway; this depends partly on the special advantages which the waterway presents in the case of traffic coming from the seaports, partly on the absence of reduced tariffs for the importation into Germany of produce capable of competing with national produce.

We have already stated (chapter I) that the part played by railways as regards the import of cereals is practically nil. The same applies to timber.

		By rail.	*By water.*
Imports of timber from Holland and Belgium into Westphalia.	1886.	480 tons.	20,000 tons.
	1906.	5,800 —	280,000 —

This phenomenon is still more marked in the case of minerals, although protectionist ideas do not have any influence.

	By rail.	*By water.*
Imports from Holland and Belgium in 1886 . .	240,000 tons.	320,000 tons.
— — — 1892 . .	609,000 —	620,000 —
— — — 1906 . .	37,000 —	2,340,000 —

The inversion which from 1892 substituted a retrogression for the progress hitherto observed in the case of imports by rail, is partly explained by the abolition, in 1893, of the rebates formerly given by the Dutch railways. These rebates had the object of ensuring the utilization, on the return journey, of the wagons used for carrying Westphalian coal which was exported. Seeing the reduction in the freights on the Rhine, which attracted all the coal traffic, the Dutch railways concluded that it was no longer to their advantage to make any efforts to retain a mineral traffic which in itself was hardly remunerative, and this traffic disappeared almost at once.

Taking it altogether, the policy of the Dutch and Prussian railways is not disconnected with the inversion which has taken place in the relative importance of the two currents, of traffic on the Rhine, from the frontier, as shown in the following table :

YEAR.	Traffic	
	down-river.	up-river.
1875	1,772,000 tons.	741,000 tons.
1906	7,690,000 —	13,404,000 —

It does not seem that the competition of the Prussian railways has had any very definite influence on the Elbe traffic, except perhaps as regards sugar for export; the amount conveyed by water, although not diminished in absolute amount, has ceased to progress; it formed 60 per cent of the down-river traffic from Magdeburg in 1897, and only 40 per cent of it in 1906.

This competition appears to be more brisk on the Oder. According to information supplied by the chamber of commerce, the traffic transhipped from wagon to boat at the port of Breslau fell from 1,130,000 tons in 1894 to 629,000 tons in 1905.

Among the articles which have most suffered by this competition, there is in the first place the Silesian coal sent to Pomerania. An exceptional tariff made in order to keep out English coal, made the share of the railway amount in 1906 to 950,000 tons as against 300,000 tons carried by water, while formerly the difference was in favour of the waterways.

In order to utilize empty return wagons, a reduced tariff was made for minerals in connexion with Silesia, so that the share of the railway, in the tonnage of minerals received by Silesia, amounted to 280,000 tons in 1904, as against 86,000 tons by water.

XII. — Collaboration of the railways and the waterways.

We are in the first place going to consider under what conditions collaboration between the railways and the waterways can arise, and then how it is carried out.

A. In what cases is there collaboration? Or rather, in what cases is it to the interest of the railways to organize this collaboration?

We will distinguish between three cases :

1° The railway system in question has its greatest length at right angles to an important waterway. This is the case with the Saxon State Railway, or with the Aussig-Teplitz Railway with respect to the Elbe. This was formerly the case, as regards the lower Rhine, with the three old railway companies (the Rheinische, the Bergisch-Märkische, and the Köln-Mindener) which built the three transhipment ports Hochfeld, Duisburg and Ruhrort, which have become famous since. The same was the case with the old Hessian railway companies. This also applies to many Russian lines ending at the Volga ;

2° The railway system is in the direction continuing the waterway, or rather that part of it accessible to large boats. This is the case which arises on the Baden State Railway, as most of the Rhine navigation ceases at Mannheim. Of the 11,800,000 tons carried in 1906 on this railway, 5,760,000 tons were coming from or going to a Rhine port which in nearly all cases was but a transit point; through Mannheim alone 3,660,000 tons passed, of which 2,255,000 tons (61 per cent) were transhipped direct. The same applies, to a lesser extent, to the Alsace-Lorraine Railway, thanks to the ports of Lauterburg and Strasburg. Similarly the Bavarian State Railway receives quite an important amount of traffic from the upper Danube and will receive still more from the Main when its canalization to Aschaffenburg is completed. The Austrian railways find a feeder of the first order in the Elbe;

3° Another very frequent case is when a railway has an interest in developing its mixed traffic together with a waterway, in order to compete with another waterway or another railway.

The Prussian railways, which are as a rule but little in favour of mixed traffic, know how to make use of it if necessary. Thus they favoured at Schönebeck, on the Elbe, a short distance from the Saxon frontier, the transhipment of the goods which the reduced tariffs applicable when leaving the ports of Riesa and Dresden (1) tend to attract to the Saxon rails. They follow the same policy in order to attract to

(1) During many years the Prussian and the Saxon railways competed with each other in order to bring, by very reduced tariffs, the former to Dresden, the latter to Walwitshafen, also on the Elbe, the

Frankfort part of the traffic which the Baden State Railway attracts to Mannheim. Quite recently even, in consequence of a number of complaints made by the Breslau chamber of commerce, they have granted some reductions in the rates intended to make mixed traffic on the Oder and the Prussian railways possible, in competition with that which the Austrian railways developed on the Elbe, with transhipment at Tetschen.

Similarly the Baden railways looked with an unfavourable eye on the attempts made by Strasburg to develop the navigability of the Rhine above Mannheim. When they saw, in spite of their efforts, the success of the port of Strasburg, they built at Kehl, opposite to Strasburg, a new transhipment port; this port is intended to bring back to the Baden railways the traffic escaping Mannheim, which without that would go to Switzerland by the Alsace-Lorraine railways.

B. How is the collaboration of the two systems of carriage organized in the cases we have just described?

It is effected, on the one hand, by the installation of the transhipment ports which we have already mentioned, on the other, by the establishment of special tariffs which often take the form of transhipment tariffs, that is of tariffs only applying to goods which have come by water or are going to be sent on by water. The customer must then prove the origin or the destination of the goods.

There is a rather large number of such tariffs (*Umschlagstarif*) in Germany and Austria. We will mention some of them :

The Elbe lends itself to the establishment of such transhipment tariffs, at Dresden and Riesa (1) by the Saxon railways, and especially at Tetschen or Laube by the Austrian railways. This makes it possible to obtain very favourable rates for the export of Saxon or Austrian goods via Hamburg, by only having the reduction of the railway journey on a foreign railway.

We will give below, for different articles utilizing these tariffs, a comparison between the through rates by railway alone or by railway and waterway jointly; in the latter case we give two rates, according as hauled boats or quick boats carry the goods on the Elbe. The transhipment charges are 50 centimes per ton (4·9*d.* per English ton), those of the connecting railway 1 franc per ton (9·8*d.* per English ton). The railway rates apply to 10 ton lots. All this information has kindly been supplied by Mr. Schenker.

---

beer intended to be exported at Hamburg. This lasted until the two administrations came to an agreement in order to abolish their reduced rates; today everything goes by railway.

(1) The Saxon railways have in some cases granted secret rebates. Some years ago they granted Saxon traders, or traders domiciled in Saxony, rebates of 5 to 20 per cent of the normal tariffs in the case of certain articles (resin, petroleum, etc.), going to or coming from certain places (Munich, Bamberg, Bayreouth), if they transhipped their goods at Riesa or at Dresden. We do not know whether these rebates are always given.

ARTICLES.	Cost of carriage from Vienna to Hamburg (in francs per ton) (per English ton).		
	Slow freight by rail from Vienna to Laube and then hauled boat from Laube to Hamburg.	Slow freight by rail from Vienna to Laube and then by quick boat from Laube to Hamburg.	Slow freight, the whole way by rail.
Lard	30·13 (£1.4*s.* 5·9*d.*)	37·50 (£1.10*s.* 5·8*d.*)	45·63 (£1.17*s.* 1·1*d.*)

Mineral oil	27·88 (£1.2*s.* 7·9*d.*)	34·12 (£1.7*s.* 8·8*d.*)	38·38 (£1.11*s.* 2·4*d.*)
Wrapping paper	23·50 (19*s.* 1·2*d.*)	28·63 (£1.3*s.* 3·3*d.*)	66·50 (£2.14*s.* 0·6*d.*)
Linseed oil	38·12 (£1.10*s.* 11·8*d.*)	43·37 (£1.15*s.* 3*d.*)	43·00 (£1.14*s.* 11·4*d.*)

This great flow of traffic, by which the Elbe benefits, has raised the jealousy of the inhabitants on the banks of the Oder and the Rhine, and the latter have tried, with the help of the German railways who could not but gain by this, to attract part of this traffic. As we have seen above, the Prussian railways, after many complaints made by the Breslau chamber of commerce, granted on 1 April 1907 transhipment tariffs applying to the ports of Breslau, Pöpelwitz and Kosel, for certain articles (particularly copper, wool, cotton, phosphates, saltpetre) sent in transit from German seaports to certain stations in Austria-Hungary. Recent modifications (dated 15 March 1908 and 1 October 1908) have increased the reductions in the rates and the number of stations they apply to. In this way, the Oder and the Prussian State Railway attract a mixed traffic which otherwise would use only the Oder in order to reach the Austrian lines. But the Prussian railways, in order to avoid protectionist complaints, refuse to act similarly as regards the importation into Germany of Austrian or Hungarian goods which actually enter by way of the Elbe.

A similar tariff, but a more important one, has been established by the Austrian, Bavarian, Baden and Prussian railways, with a view to the Rhine. This is the Rhine-Main transhipment tariff (*Rhein-Main-Umschlagstarif*) which applies to goods reconsigned, both export and import, and also gives very low rates. The tranship-

ment ports in question are Mayence, Gustavsburg, and above all Mannheim and Frankfort on the Main. The reduced rates only apply to transit goods passing through Germany, such as cotton, rice, tea, pepper, coffee, articles enumerated in the previous table, etc. The German railways in this way participate in a traffic which would otherwise go to the Elbe alone. The table below gives, for the same articles as the last, a comparison of the rates (in francs per ton) between Antwerp and Bale (transit goods for Switzerland). These rates are based on a Rhine freight of 7·50 francs per ton (6*s*. 1·2*d*. per English ton); the transhipment at Mannheim costs on the average 1·25 francs per ton (1*s*. per English ton). The railway rates, which apply to 10-ton lots, show reductions of 10 to 35 per cent, as compared with the ordinary tariffs.

Linseed oil	43·7 (£1.15*s*. 6·25*d*.)	27·62 (£1.2*s*. 5·41*d*.)

The Alsace-Lorraine railways have established transhipment tariffs at Lauterburg and at Strasburg in order to get their share of this traffic, principally for relations with Switzerland. The rates are more favourable to Lauterburg, so as to give the longest possible journey to the railway. The chief reductions affect coal, petroleum and colonial provisions.

There are also some transhipment tariffs established by the Bavarian railways at Passau and at Ratisbon, on the Danube; the most favourable rates apply to Passau, which is the port nearest the Austrian frontier and hence leaves the longest possible journey to the Bavarian railways.

*

We find even more complete cases of collaboration between railways and waterways, when the carriage involves two transhipments.

We may mention the tariff applied by the German lines for diverting from the Elbe or possibly from Triest the traffic coming from Austria and going to oversea countries. This tariff, known as the Danube-Rhine-Main transhipment tariff (*Donau-Rhein-Main-Umschlagstarif*), covers two transhipments : the first, from the Danube to the railway at Ratisbon (or Passau), the second, from the railway to the Rhine or to the Main at Mannheim or at Frankfort. We give below a comparison of the cost of carriage of the same goods as before, between Antwerp and Vienna, according to whether the railway alone is used, or one or two transhipments also. This information, due to the courtesy of Mr. Schenker, is established on the basis of a freight of 7·50 to 8·75 francs per ton (6*s*. 1·2*d*. to 7*s*. 1 35*d*. per English ton) on the Rhine from Antwerp to Frankfort; a tranship rate of 1·60 francs per ton (1*s*. 3·6*d*. per English ton) and a rate for the connecting railway in the same port of 3·75, 2·50 or 1·25 francs (3*s*., 2*s*. or 1*s*.) per wagon according to the class of goods. The freight on the Danube (Ratisbon-Vienna) is taken at 10·25 francs per ton (8*s*. 3·98 *d*. per English ton); the tranship rate at Ratisbon is taken at 0·85 franc per ton (8·29*d*. per English ton) and the connecting rate at Ratisbon at 0·375 franc per ton (3·66*d*. per English ton).

All the transhipment tariffs which we have just considered are tariffs of *origin* or of *destination*, which end at the waterway. The consignor must himself attend to arranging the freight for the carriage on the water. This freight varies; the comparisons of the cost of carriage, from terminal to terminal, are only based on averages. In fact the total mixed carriage is not effected at a fixed rate, and it gives rise to the making of two transport contracts. There is another class of mixed traffic which is of an opposite character, and where there are actually *combined tariffs or tariffs common to the railways and the shipping enterprises.*

These tariffs, which are brought before our notice by the Hungarian State Railway, the Austrian State Railway, the Bavarian State Railway and the Austrian Southern Railway, only apply to the Danube; this explains itself, for this river presents this exceptional character that nearly the whole traffic on it is in the hands of two companies who can make lasting agreements with the railways and carry them out : these are the Austrian and the South German Danube navigation companies. The former deals with the Austrian and the Hungarian railways, the latter with the Bavarian railways. In both cases, the share (of the total rate) received by the navigation company is fixed in advance.

The combined tariffs with the Austrian and the Hungarian railways take into consideration a large number of routes to south Germany or to the Balkans and apply to a large number of goods, particularly to paper and to metallurgical produce.

The combined rates for the Danube and the Bavarian railways apply, up-river, to cereals, flour and oil seed going to Switzerland or south Germany. Down-river, the rates distinguish between destinations in Austria-Hungaria and destinations in the countries further down the Danube (Servia, Rumania, Bulgaria), for which the reductions in the rates are much more marked. It is in fact the traffic of these districts, which could very easily take quite a different route by going to the Black Sea.

We see that all cases of collaborations between railways and waterways are, with hardly an exception, cases of competition against another route.

THIRD PART.

Comparison of the net cost of carriage by rail and water.

I. — Utility of this comparison and method of making it.

We have tried to consider the conditions under which the traffic actually divides itself between the railway and the waterway, the influence exercised on this division by the different circumstances which occur in practice and the lines of conduct adopted by the governments or administrations concerned.

Our work would not be complete if, taking the above question, we did not try to show in what cases the one or the other way is superior from the point of view of the net cost of the carriage. Whenever any service which is essential to the public prosperity can be performed by two different agencies, apart from the particular interests which may be concerned in the one or in the other, there is from the point of view of the common wealth, one general interest : the service must be organised so as to result in the least expenditure possible, for the same satisfaction of given needs. If it were proved that in any given case, for any given kind of transport, one of the two means, the railway or the waterway, involves definitely less expenditure than the other, this would of itself prove that any organization leading to the use of the latter, rather than the former, would result in a clear loss. Such a proof would no doubt not suffice for settling all the questions involved in the policy to be adopted as regards ways of communication; but it would in any case be of considerable weight in discussing them.

We will not attempt to solve this question in a general way. As regards broken-load traffic (and we mean here by the word " broken-load " consignments of which a certain number are necessary for making up a complete train-load or a barge-load), the question would be both nearly insoluble and also not of much interest.

The question would be insoluble, for such traffic can only be carried by large undertakings, organizing regular services and having permanent installations at all the places they serve. These undertakings, utilizing one and the same staff and one and the same plant for consignments which are absolutely heterogeneous, would be quite unable to determine, out of their total expenditure, how much of it referred to each operation. What settles the rate they ask for any individual transport, is not its estimated net cost, but the estimated sum which it is possible and equitable to ask it to contribute towards the total expenditure which has to be covered.

The question would on the other hand be of no interest, for no one disputes that the railway is far better suited to this kind of traffic than the waterway, owing to the

variety and regularity of its services, owing to its aptitude to branch off so as to reach all parts of the territory, owing to the possibility of making up trains of wagons coming from everywhere and going to anywhere. No doubt at certain points shipping enterprises can be organized which can prosper by taking away from the railway some of its broken-load traffic; but it is never with a view to these services that it is proposed to construct or extend waterways, and their organization is but a subsidiary consequence of works carried out for a totally different object.

This object is the conveyance of goods in large masses, coming from or going to seaports, industrial centres and lage towns between which there are exceptionally busy currents of traffic. It is when one of these currents is not properly served that the question arises whether a waterway or a railway is better for improving the situation. It is accordingly for this kind of traffic that it is advisable to draw up a comparison of the net cost of these two ways.

In order to find the net cost of carriage proper on water, it is enough if we determine the mean freight charged for whole boat-loads, deducting the tolls if any. Under the influence of the competition between the different enterprises, large and small, which cater for that traffic, the freight necessarily approximates to the net cost. Enterprise and experience confirms in this respect what reasoning enables us to foresee. All the analyses which have been made of the elements of the net cost of water carriage under these conditions show that the freight fluctuates near the total of these elements (1), so that the annual gain of the boatman who works on his own account represents on the average fairly accurately, the pay of a workman of the same class, plus the interest and amortization of the cost of his boat. The inequalities which we have mentioned in the average level of the freights, according to district and to article, correspond to the inequalities in the net cost. These themselves result from the different conditions under which the boats work from the points of view of the cost of traction, the utilization of the staff and of the stock, etc.

On the railway, the net cost of carriage is no longer equal to the rate; it only forms the lowest limit to which it may be the railway's interest to lower the rate, rather than lose the traffic. We have said that it would be very difficult to fix this limit with accuracy for each element of a whole number of traffics including infinite varieties. But we may form a sufficiently-approximate idea for the special kind of traffic we are considering here, for that which presents itself in lots sufficiently large to have a specialized staff and stock devoted to it, so that the consignments consist, if not of whole train-loads, at least of an important number of truck-loads starting from one given station and going to another given station.

It should in the first place be noted that with this class of traffic, the loading and

(1) See more especially Mr. Plichon's rapport on the projected canal to the north of France; Chambre des Députés, 7th session, No. 2995.

the unloading of the wagons is carried out by the consignors and the consignees, just as is always the case with complete boat-loads. On the other hand, the only railways where waterway competition has to be taken into consideration are those which follow valleys or pass from one valley to another over ground sufficiently level to make it possible to run a canal across the watershed; under these conditions, railway main lines are never built with gradients exceeding 3 to 5 per mil. We can accordingly limit our examination to the case of a service not including any handling, and operated on lines with such an excellent profile.

In this examination we will successively assume two very distinct hypotheses :

1° We will in the first place consider the ordinary case, that in which the two ways between which competition can arise already exist. Assuming that it is a question of railway which already carries passengers, parcels and smaller lots of goods, we will try to take separately the traffic we are considering, in order to determine its net cost. We will compare this with the cost of similar traffic carried on a waterway.

2° We will take the case when the existing lines have arrived at the limit of their capacity and when this cannot be increased without excessive expense, on account of the difficulties which arise from the industrial development of a district and from the multiplicity of adjoining works which would render any extension ruinous. The traffic would then make necessary the construction of a new line of great capacity and built wholly for the specialized traffic we are considering; we will then try to determine what would be the cost of a new railway, on the one hand, and of a new canal, on the other.

II. — Case where traffic uses existing lines.

Taking as our basis the working conditions of the French railway systems on which heavy traffic plays a great part, we will try to estimate within what limits the net cost of this special traffic varies.

It is comparatively easy to obtain an absolute minimum by calculating what it costs the railway to run an *extra* train. We mean by extra train one which can be added to the trains already running on the line, without any alteration in the general organization of the services, without the company having to incur any expense for supplementary works, for cost of general management, for the maintenance of the way and works, for station staff. The cost then only includes the cost of the train proper.

According to the results observed on several railways and the information we have received from the heads of the departments concerned, we think we can estimate, with sufficient accuracy, the cost per train-kilometre of an extra train

weiging 1,000 tons gross, consisting of 20-ton wagons and carrying a paying load of 700 tons, running on a line with a very good profile, at a time when coal is at its average price, as follows :

Expenses special to the train (locomotive men and train men, fuel, repairs of locomotives, etc.) .	1·55 francs (1*s.* 11·95*d.* per train-mile).
Interest and maintenance of rolling stock . . .	0·90 franc (1*s.* 1·90*d.* — —).
Total. . .	2·45 francs (3*s.* 1·85*d.* per train-mile).

If we assume that the train runs back empty, the cost per kilometre (per mile) for the return falls to 2·15 francs (2*s.* 9·22*d.*), owing to the reduction in the weight hauled. The journey out and home thus costs 4·60 francs per useful kilometre (5*s.* 11·07*d.* per useful mile) or $\frac{4.60 \text{ francs}}{700} = 0{\cdot}65$ centime per ton-kilometre (0·102*d.* per English ton-mile).

Among these investigations into the net cost made at our request, we would mention a very complete one made by the French Eastern Raiway; we reproduce the essential parts of it in an appendix. The interesting feature of this work is that it leaves as little as possible to hypothesis, being based on a service which actually exists. The data concerning the organization of the time-table, the importance and the utilization of the staff and of the rolling stock, accordingly leave no room for criticism. We may add that they take into account all the elements which in practice reduce that utilization (interruption of the traffic in consequence of the application of the law of the weekly rest; rest and leave of absence of employees; repairing and cleaning the rolling stock, etc.). In its work, the French Eastern Railway has considered two instances of the carriage of minerals, the one between Hussigny or Homécourt and Lourches, 284 kilometres 176 miles), the other between Moutiers and Differdange, 83 kilometres (52 miles). Assuming that the service is stopped one day out of six in order to allow for Sundays and feast days, a net cost of 0·49 centime per ton-kilometre (0·077*d.* per English ton-mile) is obtained in the first case, and one of 0·73 centime per ton-kilometre (0·115*d.* per English ton-mile) in the second; the average in thus 0·62 centime (0·097*d.*) a figure which nearly approximates that of 0·65 centime (0·102*d.*) given above.

It is evident that this cost is never realized unless it is question, not of an occasional addition to the traffic, but of a *regular and important* traffic. Such traffic naturally involves an increase in the expenses not specialized, which must be allowed for. It is impossible to estimate the increase accurately, but an idea of it may be formed from the relative importance of the expenses concerned.

We will take from the French railway statistics for 1907 the net cost per train-kilometre on the two systems the Northern and the Eastern, which are those on

which the traffic we are considering has most importance. These means are calculated for the whole of services, both passenger and goods.

DEPARTMENT.	French Northern.	French Eastern.
General management	0·22 franc (3·399*d.*)	0 21 franc (3·244*d.*)
Traffic	0·75 — (11·587*d.*)	0·87 — (1*s.* 1·441*d.*)
Rolling stock and locomotive	1·06 francs (1*s.* 4·376*d.*)	0·81 — (1*s.* 0·514*d.*)
Way and works	0 36 franc (5·562*d.*)	0·41 — (6·334*d.*)
Miscellaneous	0·02 — (0·309*d.*)	0·06 — (0·927*d.*)
Total. . .	2·41 francs (3*s.* 1·233*d.*).	2·36 francs (3*s.* 0·460*d.*)

The estimate of the expenses *special* to a complete train of heavy goods, which we have given above, is much greater than the *mean* cost to the *rolling stock and locomotive department*, per train-kilometre, given above; two circumstances explain this : 1° a train much heavier than the mean train is considered; 2° the figures first given include the train men, who are charged for under the traffic department, while the rolling stock and locomotive department only pays for the drivers and firemen and the staff at the locomotive sheds.

As regards the *traffic* department, we would on the contrary only have to reckon with expenses much below the mean, in the case of the special traffic which we are considering. The principal expenses, in fact, which the statistics include under this head are :

The staff which does the secretarial work at departure and at arrival, delivers tickets, checks the consignments, works out the rates; this work, which is very expensive and complicated in the case of a broken-load or a passenger train, hardly represents anything in the case of a train consisting of identical consignments which are very few in number.

The handling is in this case done by the parties concerned.

The sorting, marshalling and making-up operations at the start, en route, and on arrival, are in this case practically nil as the train runs from terminal to terminal and as the sets of wagons are often got ready on private sidings.

As regards the train conductors and guards, we have already allowed for them in the figure of 2·45 francs (3*s.* 1·85*d.* per train-mile) previously given as the expenses special to the train considered.

We therefore think we will be much above the truth if we add to the last figure, for the traffic expenses which do not figure there, one third of the mean expenses, per train-kilometre, corresponding to the operations included under the heading of traffic for the whole of the system.

As regards management and miscellaneous expenses, we will take the mean without modification. By taking, in the case of traffic not involving any complication, its proportional part in the expenses (which include the payments towards the pensions of all the traffic staff, although this traffic hardly affects it), we shall be above the truth rather than below.

We will do the same as regards the cost of way and works. A heavy train wears the line more than a light one; but the deterioration of the roadbed and of the track itself depends on other factors besides the importance of the traffic, and in any case, the corresponding expenses are far from increasing in the same proportion; they contain a fixed part which, divided for each line by the number of trains, gives a quotient which is the lower the greater the traffic. It is thus probable that the extra cost of maintenance of a busy line resulting from the passage of a heavy train exceeds the mean cost of maintenance of the system, referred to the mean train-kilometre (train-mile). Moreover, the traffic which we are considering hardly makes any use of any of the buildings. Hence we shall thus allow for this item very fully if we take half of the figure given in the statistics.

By adding together all these different items, we thus find :

On the French Northern. . . .	85 centimes per train-kilometre	(1*s.* 1·13*d.* per train-mile).
On the French Eastern	97 —	—	(1*s.* 2·98*d.* —).

Dividing the supplementary expenditure so calculated for 2 train-kilometres (1·24 train-mile) (there and back) by 700, we find we have to add 0·24 centime (0·038*d.*) in the case of the French Northern and 0·28 centime (0·044*d.*) in that of the French Eastern, to the figure of 0·65 centime per ton-kilometre (0·102*d.* per English ton-mile).

A third element has still to be take into consideration : the cost of supplementary works (enlarging stations, duplicating tracks, etc.) made necessary by the growth in the traffic.

Let us compare, for the purpose, the progress of the traffic, and the expenditure made on supplementary works on the French Northern and Eastern systems during the last twenty years. We find :

	French Northern.	*French Eastern.*
Increase in the slow-freight traffic, from 1888 to 1907 inclusive (in thousands of ton-kilometres) (in thousands of English ton-miles).	1,926 (1,178)	1,830 (1,119)
Increase in the passenger traffic from 1888 to 1907 inclusive (in thousands of passenger-kilometres) (in thousands of passenger-miles)	1,456 (905)	1,120 (696)
Expenditure on supplementary works, from 1 January 1888 to 31 December 1907 (in millions of francs)	207 (£8,280,000)	134 (£5,360,000)

In the absence of anything to guide us, let us assume that the expenditure on supplementary works is divided between the two services (passengers and slow freight) proportionately to the new kilometre units, and that the traffic we are considering takes its proportional part. This seems a rather large allowance, for even if the development of this heavy traffic has necessitated considerable expenditure, particularly on the construction and extension of yards and shunting and sorting sidings, this expenditure per kilometre unit is certainly less than that due to the development of the passenger traffic. Near great towns, particularly in the case of Paris, the suburban service has developed very quickly, making extensive and very costly work necessary for extending the large stations and their approaches. The very short mean distance travelled by the suburban passengers makes these expenses enormous, if referred to the passenger-kilometre (1). If then we assume that the expenditure on supplementary works is the same per passenger-kilometre as per ton-kilometre, we probably obtain too high a figure for the latter kind of traffic.

It may be noted, on the other hand, that we make no deductions for those supplementary works which are only for the quick-freight traffic, the cattle traffic, etc., traffic which brings in 10 per cent of the receipts and which has developed particularly quickly during the last twenty years. The positive error, in calculating the fraction of the expenditure due to each kilometre unit of the additional traffic, which results from this omission, more than counterbalances the negative error we incur in not deducting from the total increase in the number of kilometre units the part due to the new lines opened during the last twenty years. This deduction would in fact be very small, as the new lines are not extensive and are but little used on the systems which we are considering; the most numerous and the most important, in that district, are those which have been constructed exclusively for strategic purposes and which have hardly contributed to the development of the traffic.

Two exceptions have however to be made. On the French Northern, additional lines are at present being built, intended to relieve the main lines, from the great coal basin to Paris; but none of these were yet open to traffic in 1907, so that they in no way helped to carry the traffic in that year. On the French Eastern, several new lines have been built in the last few years in order to develop the Briey basin; the expenditure incurred for the purpose really corresponds to a new and important traffic. We will accordingly add the total expenditure on these lines to the account for supplementary works on the French Eastern, namely 34 million francs (£1,360,000), remarking however that this expenditure will make it possible to deal with a large traffic which as yet is only beginning to develop. This addition increases the expenditure in supplementary works, on the French Eastern Railway,

(1) The mean distance per passenger, in 1906, was 26 kilometres (16 miles) on the French Northern and 28 kilometres (17 miles) on the French Eastern.

incurred to deal with the growth of the traffic from 1887 to 1907, from 134 to 168 million francs (£5,360,000 to £6,720,000).

The annual charges corresponding to the supplementary works of this period, calculated at the rate of 4 per cent for interest and amortization, then represent :

On the Northern	8,280,000 francs	(£331,200)
On the Eastern	6,720,000 —	(£268,800)

Divided by the number of additional kilometre units of traffic, this gives for each additional kilometre unit :

On the Northern	0.24 centime	(0·038*d.* per English ton-mile)
On the Eastern	0·26 —	(0·041*d.* — —)

By adding, in the case of each railway, to the estimate of the special expenditure caused by running a heavy train of the modern type, the two other elements which enter into the net cost per kilometre (per English ton-mile), we obtain :

On the Northern	0·65 + 0·24 + 0·24 = 1·13 centimes	(0·177*d.*)
On the Eastern	0·65 + 0·28 + 0·26 = 1·19 —	(0·187*d.*)

No doubt, these figures are not obtained from an exact division of the total expenditure between the different kinds of traffic, which is practically impossible; a similar analysis, carried out on other lines, would no doubt give other results. The explanations we have given however show that the estimate we have arrived at errs on the positive rather than on the negative side.

It may thus be finally asserted that the net cost of carrying a ton of coal or mineral 1 kilometre, on railway lines competing with waterways, when consignments of a number of truck-loads, of an importance comparable with barge-loads, are dealt with, will not exceed from 1·10 to 1 20 centimes (0·173*d.* to 0·188*d.* per English ton-mile).

If we assume that on the return journey a sum would be earned only equal to one fifth of that earned on the out journey, this maximum would fall to between 0·90 and 1 centime per ton-kilometre (0·141*d.* and 0·157*d.* per English ton-mile).

This rate is materially higher than the freight paid for similar traffic on the great European free-running rivers, the Volga, the Rhine, the Elbe. It is approximately equal to the normal freight paid on the Seine and on the best canals on the north and the east of France. It is distinctly lower than the freight on the rivers which form waterways of the second order from the point of view of their technical qualities. But it must be noted that we have included, in the case of railways, every kind of expenditure. On the other hand, apart from certain exceptions exceedingly rare in France, the freight includes nothing for the cost of management and maintenance of the line, nothing for the cost of supplementary works, the duplicating of

locks, etc., which any material increase in the traffic will make necessary. It may hence be asserted that the total expenditure required for carrying the same amount of traffic is in France nearly always less if a railway is used than if a waterway is used. Even assuming that the latter already exists and that it can carry the traffic competed for without any increase in the cost of construction and maintenance which falls on the State, and that on the contrary, on the railway, the traffic causes an increase in the cost of maintenance and of supplementary works, there will generally be a slight economy in adopting the latter; as soon as any supplementary expenditure has to be incurred in the case of waterways, the difference becomes very appreciable.

It follows from this that wherever the two ways coexist, the railway should attract, without suffering any loss, the traffic which goes to the waterway, by offering equally low rates, with all the advantage of regularity and speed, and that there would result, for the whole of the common wealth, a material saving in the amount spent in carrying the traffic. It must however be remarked that such low rates could not be normally admitted as the bases of the tariffs. It is in fact necessary that the railways should remunerate their construction capital out of their receipts, and if, in order to obtain traffic which they might miss, they can content themselves in the case of that traffic with a small or even infinitesimal profit, they could not carry in the same way, at very near cost price, the millions of tons capable of contributing to a greater or less extent towards the payment of the permanent charges on the railway system, unless the State placed the burden of paying the interest and amortization on the tax-payers, as it nearly always has done in the case of waterways. In order therefore to make it really possible for a railway to take away the traffic competed for from the waterway, it must be able to grant reduced rates applying to this traffic alone. It will in all cases find great difficulty in doing so; in France, in particular, such reductions would not be authorized, for they would seem, and with some reason, to benefit to an excessive extent the manufacturers concerned. The privilege which public opinion grants unconcernedly when it takes the form of advantages granted to waterways, would raise its reprobation if it resulted from railway rates; the public would very soon require that the reduced rates should be made general, assuming that the authorities would have authorized them to be applied to certain lines only. The administrations which operate the railway must consequently, when they are competing with waterways, take into consideration in their calculations the reaction exercised by any reduction in the tariffs on the traffic which is not competed for.

Finally we may remark that in comparing waterway and railway rates there is another element, continually becoming more and more important, which is generally left out of consideration; namely the legal protection of the railway employees. Even if we leave this protection out of consideration, the railway employees are already much better remunerated than the waterway employees; it is natural that the former, who often have delicate and very responsible work to do, should earn in

a year a good deal more than the latter, sometimes two or three times as much. The railway administrations are led to pay these salaries or wages, without any intervention of the public authorities, because they represent the value of the work done; that is a normal element of the net cost, and one can only congratulate oneself on having a large number of workers well paid and well treated. But on the other hand, all the measures of regulation or legal protection affecting railway employees (the tenth day's work rest of drivers and firemen, the limitation of the of work per day, the fixing of a maximum age giving a right to a pension, the fixing of a minimum rate for that pension, etc.) artificially augment the cost of carriage on railways as compared with that on waterways, as, in France at least, there is nothing of the sort in the case of watermen. Without discussing to what extent these measures are justified or not, we have to state they are continually taking a far greater development, capable of modifying, to the disadvantage of the railway, the comparison of the net cost which we have just made. Nobody disputes that it would be impossible to burden the water traffic with the extra charges necessary for benefiting the watermen to the same extent, and that this would kill the water traffic. But it must be noted that it would be considerably to the advantage, not only of the taxpayers called upon to pay the charges not covered by the tolls, but also to that of the working classes, that it should be the railway, rather than the waterway, that developped its traffic and consequently its staff.

III. — Case where it is necessary to make a new way on account of the development of heavy traffic.

Let us now assume that the lines which could be utilized have arrived at the limit of their capacity, or do not present the technical conditions necessary for a heavy traffic. It is then necessary to make a new line, either a railway or a canal. In practice, if a railway is built, it is utilized not only for the traffic which could go on a canal, but also for passenger and quick freight traffic. If this is done, it is evident that this solution is more advantageous than if a line is built and used for heavy traffic only; but this procedure makes it difficult to compare the railway and the waterway, because an instrument intended for a very complex service, other things being equal, is necessarily more expensive than an instrument only intended for a very simple service.

In order to establish a useful comparison, we will assume that a railway has been built for heavy traffic only and that it conveys neither parcels nor passengers. Such cases exist in America (for instance, the line from Pittsburg to Lake Erie), but there is hardly an instance of any importance in Europe. It is however such an instance which has to be examined, if we want to ascertain whether it is a railway or a canal which can carry, under the most economical conditions, the excess of heavy traffic existing lines can no longer deal with.

In the absence of any practical instance, we have requested the French Northern

Railway to calculate the net cost of carriage of coal from the north to Paris, assuming the traffic concentrated on a specialized line, and not carrying any traffic in the opposite direction. We reproduce its answer in an appendix.

This answer is of considerable value, for on the one hand, the operating and traction expenses are based on the results of experience; and on the other, the calculation of the capital outlay necessary is based on the figures of the Picardy-Flanders line, where the traffic was insignificant until a recent period when the administration decided to equip it in order to divert on to it a very large coal traffic, so that it is only necesary to deduct the cost of buildings from the total expenditure on building and improving the line in order to obtain a very accurate estimate of the cost of a line specialzed for heavy traffic.

As in all investigations of this kind, it is possible to criticize some of the figures. It may be asked whether the total time admitted for the round trip (two days) is not rather short, as on the existing railway this takes at least three days, including the stop at the mine. The assumption of an end-to-end traffic, without junctions or crossings, is evidently favourable to the railway. On the other hand, it must be noted that in a comparison with a waterway, it was not necessary to assume that the railway should be equipped so as to be able to cope with the maximum traffic which arises at certain seasons : the waterway is not compelled the cope with exceptional demands, for it adjusts the irregularities of its traffic by putting off what it cannot take, and, in the case of the railway, an assumption of nearly regular traffic would have resulted in a great saving in rolling stock. On the other hand, the calculation has been made for the traffic which at present exists, namely, for 3 million tons of coal; now all that part of the expenditure relating to the construction of the line would suffice, without increase, for a considerable development of the traffic. Taking all this into consideration, we think that we can accept the figure of 1 centime per ton-kilometre (0·157*d*. per English ton-mile), which the Northern Railway arrives at (see appendix II), as very near the truth with the existing traffic, and capable of very appreciable reduction as the traffic increased.

It is interesting to compare this result with that arrived at in a recent work, entitled *Massen-Güterbahnen*, by Messrs. Rathenau and Cauer (Julius Springer, Berlin 1909) (1). The object of the authors was to investigate what would be the normal cost per ton-kilometre on a standard-gauge railway line, connecting the Ruhr basin and Berlin, and replacing the « Mittelland » canal, in part voted in 1905. This railway would only have gradients of 2 per mil, curves with radii of 3,000 metres (150 chains), no level crossings, and a station at every 55 kilometres (34 miles). The cost of construction would be 500,000 francs per kilometre (£32,186 per mile). As soon as opened, this line would carry a traffic of 10 million tons, one fifth of this being in the return direction. The traffic would be so distributed that at the busiest time of the year it would be 50 per cent greater than at the slackest. The authors

(1) See *Bulletin of the Railway Congress*, No. of January, 1910, p. 518.

assume that this traffic, brought to the stations from private sidings, would be conveyed by trains with a paying load of 1,600 tons, carried in 40-ton wagons, at a speed of 30 kilometres (18·6 miles) per hour. The block-system would have to be installed

This investigation, which is also based on applying to a particular instance the results of general experience and practice, differs from the instance previously given in the fact that it does not assume a uniform end-to-end traffic. The net cost varies naturally with the distances taken, as shown in the following table :

Cost of carriage per ton-kilometre (per English ton-mile) at a distance of.	500 kilom. (310 miles) on the average :	0·91 centime	(0 143*d.*)
	390 — (242 —) —	0·97 —	(0·152*d.*)
	280 (174)	1·10 centimes	(0·173*d.*)
	170 — (106 —) —	1·37 —	(0 215*d.*)

These figures are absolutely comparable with those given by the French Northern Railway. It is interesting to observe this agreement. It should be added that the comparison we have just made only applies to a new line, built for carrying a very heavy tonnage. Hence it can only be applied in a very few cases, for instance the "Mittelland" canal of Germany, the "Nord" canal of France and the "Nord-Est" canal of France.

We see that even taking cost of construction into account, the total net cost of carriage by rail remains comparable with the freight on the best existing canals and on ordinary rivers, this freight being taken by itself, no allowance being made for the capital expenditure as well as for the cost of maintenance and management of the waterway.

But in practice, unless in the case of a free-running river where a large surface of water supplies a way of indefinite capacity, it may be assumed that where railways are overloaded, the waterways are so also. The question which then arises is whether it is better to duplicate the railway or the canal (this is the case of the "Nord" canal in France), or whether it is better to duplicate an overloaded railway or build a canal in a direction when none as yet exists, as Germany is now doing.

A canal can then be built accessible to boats taking from 600 to 700 tons; mechanical traction can be reduced to 0·6 or 0·7 centime (0·094*d.* or 0·110*d.* per English ton-mile), which compares with the outlay of the rolling stock and locomotive department on the railway; these are the rates which it is hoped to obtain on the German canals recently decided on. But these canals, in spite of the easy ground, are estimated to cost over 600,000 francs per kilometre (£38,620 per mile). The new "Nord" canal to Paris, through more irregular country, was originally estimated to cost the same amount, although only built for 300-ton boats. It is already certain that this estimate will be largely exceeded in both cases.

Nobody on the other hand will maintain that from the point of view of capacity for traffic, a canal is superior to a railway on which only trains used for one and the same service run, and on which the movement of the slow-freight trains will

never be interrupted in order to allow a passenger train to pass. The capital charges, *per ton of capacity*, will thus incontestably be greater in the case of a canal than in that of a railway used only for one and the same kind of traffic.

It is interesting to find that taking it altogether the estimates made by the French Northern Railway and by Messrs. Rathenau and Cauer, for the case of a new line, are quite of the same order of magnitude, as those which we arrived at in the case of traffic adding itself to that on an existing line, used for railway traffic of all kinds. In both cases we find that the cost on the railway, interest on new works included, is lower rather than higher than the freight charged on all the canals opened up till now, which does not include cost of construction. It is no doubt hoped in the case of the new canals that freight may be obtained approximately equal to the cost incurred by the rolling stock and locomotive department in the case of heavy traffic on railways; but those hopes are not yet realized, and in any case the difference of capacity of lines constructed at an equal cost would leave the advantage to the railways, assuming naturally that the traffic to be carried will one day become sufficiently large to utilize that great capacity.

Thus if all expenses are included, it certainly seems that even in the case of heavy traffic which shipping claims as peculiarly its own, the railway remains the most economic carrying instrument, in all the places where nature has not provided large rivers with a gentle fall.

In the different preceding comparisons, we have only considered the cost per kilometre. We have not taken into account the savings resulting from the fact that the railway is generally shorter, and from the facilities afforded by its numerous branches to distribute without transhipment throughout the whole district the goods brought on its main line. Even if we leave these elements out of consideration, which are of considerable importance, one is right in thinking that under normal conditions the railway is the economical way, while it is at the same time the quick and the regular way. If the opposite opinion is widely held, it is due to the fact, generally forgotten, that the railway rates nearly always include the remuneration of the capital stock, while in the case of waterways, this is nearly always left to the taxpayers.

APPENDIX I.

Summary of an investigation made by the French Eastern Railway into the net cost, per train-kilometre, of a train weighing 1,000 tons gross, carrying a regular heavy-goods traffic on a line with a good profile.

We have requested the proper departments of the French Eastern Railway to make this investigation, taking as their basis as nearly as possible an actually-existing service and adopting, for the different elements of the expenditure, the classification of table 19bis of the French railway statistics, which corresponds to the following articles in table XIII of the report to the meeting of the shareholders of the French Eastern Railway Company.

Classification of table No. of the French railway service. (*19bis (old form)*; *35 (new form)*)	*Corresponding articles in table XIII of the report to the meeting of the shareholders.*
Staff (including the premium for saving fuel). . . .	Art. 1. — Central administration (staff). Art. 3. — District administration (staff). Art. 5. — Traction (staff).
Fuel consumed by the locomotives.	Art. 6. — Traction (fuel for the locomotives).
Maintenance of the locomotives, carriages and wagons (including handling)	Art. 9. — Stock (upkeep of locomotives and tenders). Art. 10. — Stock (upkeep of carriages and wagons).
Sundry expenses	Art. 2. — Central administration (office expenses and miscellaneous) Art. 4. — District administration (office expenses and miscellaneous). Art. 7. — Traction (lubrication, lighting, water, sand and miscellaneous articles of consumption). Art. 8. — Traction (miscellaneous "general expenses of the sheds, upkeep, renewal of tools and appliances, heating, lighting, etc."). Art. 11. — Renewal of rolling stock.

In order to have more precise information, we requested the company to replace article 11 of the report by the direct calculation of the interest and amortization of the material, assuming the rate of interest to be 4 per cent and the amortization to take forty years in the case of locomotives and fifty years in that of wagons. We assumed the train weighing 1,000 tons gross to consist of 20-ton wagons, which, with the Eastern rolling stock, corresponds to a paying load of 680 tons. We requested that to these expenses there should be added the cost of train staff (belonging to the traffic department). All the French regulations on the safety and the composition of trains, and on the rests of the employees, were to be taken into consideration. The calculations were to be based on the average price paid for coal and for rolling stock. Finally, it was to be assumed that the train was to run back empty.

The French Eastern answered our request in the most complete way, by investi-

gating the net cost of the two existing services for the carriage of minerals, one between Hussigny or Homécourt and Lourches (284 kilometres [176 miles]), the other between Moutiers and Differdange (83 kilometres [52 miles]).

We reproduce the first of these two investigations *in full :*

Service of trains carrying minerals between Hussigny or Homécourt and Lourches, a distance of 284 kilometres (176 miles).

(Two trains of 1,000 tons per day.)

For hauling these trains 9·2 locomotives and 9·2 locomotive crews are required. — The locomotives are of type 4,000, with four coupled wheels, compound, with four cylinders. — The number of these locomotives has to be increased by 25 per cent for reserves, unavailabilities and repairs.

The locomotive staff, 9·2 crews, has to be increased by 10 per cent for leaves and illnesses.

The rolling stock consists of four sets of wagons. — The wagons are 20-ton wagons and each set consists of 34 wagons and 1 van. — The number of these wagons has to be increased by 10 per cent for repairs, examinations and immobilizations.

IMPORTANT NOTE. — The list of expenses given below does not include the expenses of the traffic and the way departments (except for the train men, added at the end).

Among the rolling stock and traction expenses, there are not included the following items : contributions of the company to pension and provident funds; general expenses of the central administration of the company; assistance, contributions towards family expenses, etc. ; medical service; interest on the stores ; upkeep of buildings ; interest and amortization of buildings; interest and amortization of the tools and appliances at the workshops and sheds; taxes of all kinds; fire insurance; accident insurance; contribution of 7·50 per cent of the fixed salaries towards the insurance funds of the company's employees.

Determination of the cost of a service of trains for carrying minerals between Hussigny or Homécourt and Lourches (284 kilometres [176 miles]).

		Cost	
		total annual.	per kilometre (per mile) of loaded train.
Service.	Two trains per day : 2 × 284 (176) = 568 (352) loaded trains.		
	1 × 284 (176) = 284 (176) empty trains.		
	1 × 284 (176) = 284 (176) locomotives running light.		
	1,136 (704) (total distance run by locomotives).		
	Annual distance run :		
	Loaded trains . 568 (352) = 207,320 (128,825)		
	Empty trains. . 284 (176) × 365 days = 103,660 (64,412.5) = 414,640 km. (257,650 miles.)		
	Locomotives running light . . 284 (176) = 103,660 (64,412.5)

		Francs.	Francs.
	Brought forward. . .	405,223·00 (£16,208.18s. 4·82d.)	1·95457 (2s. 6·1970d.)
Miscellaneous expenses.	Art. 2. — Central services (official expenses and miscellaneous) : Cost per kilometre in 1908 . . 0·00149 fr.		
	Art. 4. — District services (office expenses and miscellaneous) : Cost per kilometre in 1908 . . 0·00098 fr.		
	Art. 7. — Traction (lubrication, lighting, water, etc.) : Cost per kilometre in 1908 . . 0·02363 fr. — 0·03592 fr. × 414,640 km. = 14,893·87 fr.	14,893·87 (£595.15s. 1·15d.)	0·07184 (1·1099d.)
	Art. 8. — Traction (heating, lighting, upkeep and renewal of tools and appliances at the depots) : Cost per kilometre in 1908 . . 0·00982 fr.		
	referred to the distance run by loaded trains, this gives $\frac{14,893·87 \text{ fr.}}{207,320 \text{ km.}} = 0·07184$ fr.		
Interest and amortization.	1° Locomotives and tenders.		
	Number of locomotives . . . . . $9·2\left(1+\frac{1}{4}\right) = 11·50$		
	Average weight of a locomotive, type 4000 . . . . . 67,473 kilograms.		
	Average weight of a tender holding 13 cubic metres (2,860 English gallons) . . . . . 14,905 —		
	Average price of a locomotive. . . . . 1·85 fr. × 67,473 kg. = 125,000 francs.		
	Average price of a tender . . . . . 1·00 fr. × 14,905 kg. = 15,000 —		
	Together (locomotive plus tender). . . 140,000 francs.		
	Total value of locomotives and tenders required : 140,000 fr. × 11·5 = 1,610,000 fr.		
	Interest and amortization in forty years, at 4 per cent (4·00 fr. + 1·0523) = 5·0523 fr. p. c.		
	or altogether. . . . . $\frac{1,610,000 \text{ fr.} \times 5·0523}{100} = 81,342·03$ fr.	118,722·03 (£4,748.17s. 7·40d.)	0·57265 (8·8471d.)
	referred to the distance run by loaded trains, this gives. . . $\frac{81,342·03 \text{ fr.}}{207,320 \text{ km.}} = 0·39235$ fr.		
	2° Wagons.		
	Cost of a set (35 wagons) . . . . . 182,500 fr.		
	Increase of one tenth for repairs, inspection and immobilization 18,250 fr. — 200,750 fr.		
	this gives for four sets. . . . . 200,750 fr. × 4 = 803,000 fr.		
	Interest and amortization in fifty years, at 4 per cent (4·00 fr. + 0·655) = 4·655 fr. p. c.		
	whence an expenditure of . . . . . $\frac{803,000 \text{ fr.} \times 4·655}{100} = 37,380$ fr.		
	referred to the distance run by loaded trains, this gives . . $\frac{37,380 \text{ fr.}}{207,320 \text{ km.}} = 0·18030$ fr.		
Train staff.	8 chief conductors at 2,600 francs = ... 20,800 fr.		
	29 brakesmen at 2,100 francs = ... 60,900 fr.		
	Total expenses . . . 81,700 fr.	81,700·00 (£3,268)	0·39408 (6·0883d.)
	referred to the distance run by loaded trains, this gives . . $\frac{81,700 \text{ fr.}}{207,320 \text{ km.}} = 0·39408$ fr.		
	Total. . .	620,538·90 (£24,821.11s. 1·44d.)	2·99314 (3s. 10·2423d.)

The second investigation is made, on exactly the same plan, in the case of traffic between Moutiers and Differdange (83 kilometres [52 miles]); it results in a cost of 4·33 francs per useful train-kilometre (5*s.* 6·90*d.* per train-mile). It is at once clear, if the two services are compared, what influence the length of the journey exercises on the net cost of the traffic, and to what extent the marked reduction in the rate per kilometre in the case of longer distances is justified. The reduction in the net cost when the distance increases is easily explained by the better utilization of the staff and of the rolling stock. The difference is shown in the following table :

ANNUAL DISTANCE RUN (in kilometres [in miles]).	*First instance* (284 kilometres [176 miles]).	*Second instance* (83 kilometres [52 miles]).
Of each locomotive	36,055 (22,404)	17,626 (10,952)
— set of wagons	103,660 (64,413)	60,590 (37,650)
— locomotive crew	40,972 (25,459)	20,029 (12,446)
— train man	51,830 (32,206)	30,295 (18,825)

The net costs given above have been calculated on the assumption that the service is kept up without interruption on the three hundred and sixty-five days of the year. The company remarks that in reality such a service would hardly be operated on more than three hundred working days; hence it is necessary to reduce the annual distance run by the trains by one sixth, without any serious saving resulting except in fuel.

By introducing these two corrections, we obtain, for a year of three hundred days :

—	*First instance* (284 kilometres [176 miles]).	*Second instance* (83 kilometres [52 miles]).
Annual distance run by loaded trains, in kilom. (in miles)	172,767 (107,354)	50,492 (31,375)
— cost, in francs (in £)	579,842 (300,304)	251,722 (156,416)
— cost, per kilometre (per mile) of loaded trains, in francs	3 36 (4*s.* 3·910*d.*)	4·98 (6*s.* 4·938*d.*)

If we divide the cost per useful train-kilometre by the number of tons hauled (680), we obtain the net cost per ton-kilometre (per English ton-mile):

In the first case	0·494 centime	(0·078*d.*)
In the second case	0·732 —	(0·115*d.*)
Average	0·613 —	(0·096*d.*)

APPENDIX II.

Note by the French Northern Railway on the net cost of carrying coal on a line specially built for the purpose, capital charges included.

The assumption made is as follows :

All the consignments of coal and coke going from the coal yards in the Pas-de-Calais department to Paris (La Chapelle, La Plaine, Saint-Ouen, Champ-de-Mars, Clichy-Batignolles, locomotive coal included) and to the places beyond Paris to the other systems, via Bourget and La Chapelle, are supposed to be concentrated at Lens; the total tonnage, according to the 1907 figures, being in round figures 3 million tons.

This traffic is supposed to go from Lens to Paris (La Chapelle) via Corbehem (by Lens-Brebières), Montdidier (Picardy-Flanders) and Ormoy, the total distance being 260 kilometres (162 miles).

The examination of the expenses comes under the heads of capital outlay, working expenses and annual charges of the capital.

The round figure of 267,000 francs per kilometre (£17,187 per mile) may be adopted as the cost of construction of the line; this is approximately what the Picardy-Flanders line cost, after deduction of cost of buildings and of sidings at stations, but including the cost of the duplication which is now being carried out. The two terminal stations (Lens and La Chapelle in Paris), may be estimated, including the buildings, the sorting sidings and the appliances, at 600,000 francs (£24,000) in the case of Lens and 2,400,000 francs (£96,000) in that of La Chapelle, or 3 million francs (£120,000) the two.

Assuming the line to be equipped with a semaphore at every 5 kilometres (3 miles), the 260 kilometres (162 miles) require 52 semaphores costing 8,000 francs (£320) each (disks, semaphores and signal cabins included), or 416,000 francs (£16,640) altogether.

We may assume that three locomotive depots are required, two larger ones at the two terminals and one at the middle of the distance, including the necessary sidings, workshops, sleeping quarters and buildings for the staff: these will cost on the average 500,000 francs (£20,000) each, or 1,500,000 francs (£60,000) for the lot.

The Picardy-Flanders line, after the present works and rectifications have been carried out, will make it possible to haul 900 tons by means of locomotives of the type 6,000. Assuming the paying load to be 600 tons, 3 million tons per year would correspond to a traffic of $\frac{3,000,000}{365}$ tons per day, if the traffic were uniform throughout the year. But actually the experience acquired on the French Northern Railway shows that it is necessary to be so equipped as to make it possible to deal on some days with $\frac{1}{220}$ of the annual traffic. Consequently it is necessary to be equipped for $\frac{3,000,000}{220} = 13,636$ tons, or say 23 trains, each with a paying load of 600 tons, per day.

About 50 locomotives costing 115,500 francs (£4,620) each are required for this traffic;

total 5,775,000 francs (£231,000). The stock necessary is represented by 1,500 tip wagons, taking 20 tons each; 200 of these must be fitted with brakes. These cost :

1,300 tip wagons at 3,796 francs (£151.17*s.*). . .	4,934,000 francs	(£197,360)
200 — at 4,368 — (£174.14*s.*). . .	873,600 —	(£34,944)
50 vans at 8,282 — (£331.6*s.*) . . .	414,100 —	(£16,564)

The capital outlay accordingly sums up as follows :

Line	69,420,000 francs	(£2,776,800)
Terminal stations	3,000,000 —	(£120,000)
Signals	416,000 —	(£16,640)
Depots and workshops.	1,500,000 —	(£60,000)
50 locomotives	5,775,000 —	(£231,000)
1,300 tip wagons, 20 tons.	4,934,000 —	(£197,360)
200 — 20 tons with brake . . .	873,600 —	(£34,944)
50 vans	414,100 —	(£16,564)
Total. . .	86,332,700 francs	(£3,449,308)

WORKING EXPENSES.

Upkeep.

Upkeep of the line, 1 per cent of cost of construction. . . .	694,200 francs	(£27,768)
— — stations, 2 per cent of cost of construction . .	60,000 —	(£2,400)
— — signalling system, 2 per cent	8,320 —	(£332.16*s.*)
— — depots, 2 per cent.	30,000 —	(£1,200)
— — locomotives and rolling stock, at 40 centimes for 1,315,600 train-kilometres (3·84*d.* for 817,490 train-miles), loaded, and at 20 centimes for 1,315,600 train-kilometres (1·92*d.* for 817,490 train-miles), empty.	789,360 —	(£31,574.8*s.*)
Lighting and heating the stations (taking the annual expenses of two equivalent stations on the Northern system) . . .	79,660 —	(£3,186.8*s.*)

Cost of staff.

Central staff.	20,000 francs	(£8,000).
The station staff may be estimated by taking for the station-masters and assistant station-masters that part of the general service at Lens station dealing with the coal traffic, namely 46,680 francs (£1,867.4*s.*), and assuming that the lower-grade employees include one chief inspector, one chief switchman, four pointsmen, five gangs, two foremen; per station; this, at the average pay of such men on the French Northern, comes to 65,626 francs (£2,625) per station, or for the two stations	131,252 —	(£5,250.2*s.*)
104 signalmen at 1,266 francs (£50.13*s.*) each, for the 52 signal cabins.	131,664 —	(£5,266.8*s.*)

Train staff.

The train staff consists of :

60 chief-conductors	at 2,650 francs (£106)	159,000 francs	(£6,360)
60 brakesmen	at 2,026 — (£81.1*s.*). . . .	121,560 —	(£4,862.8*s.*)
60 drivers	at 3,880 — (£155.4*s.*) . . .	232,800 —	(£9,312)
60 firemen	at 2,520 — (£100.16*s.*). . .	151,200 —	(£6,048)
	Total. . .	664,560 francs	(£26,582.8*s.*)

Cost of traction.

The cost of traction may be estimated at 33 centimes per kilometre (5·871*d.* per mile) of loaded train and at 18 centimes per kilometre (2·781*d.* per mile) of empty train; total for 1,315,600 train-kilometres (817,490 train-miles) loaded and 1,315,600 train-kilometres (817,490 train-miles) empty . . . . . 736,736 francs (£29,469.9*s.*)

The cost of lubrication at 2 centimes per kilometre (0·309*d.* per mile) amounts to. . . . . 26,312 — (£1,052.10*s.*)

The working expenses thus sum up as follows :

Upkeep of line.	694,200 francs	(£27,768)
— of stations	60,000 —	(£2,400)
— of signalling system.	8,320 —	(£332.16*s.*)
— of depots	30,000 —	(£1,200)
— of locomotives and rolling stock. . . .	789,360 —	(£31,574.8*s.*)
Lighting and heating stations	79,660 —	(£3,186.8*s.*)
Central staff.	20,000 — (1)	(£800)
Station staff.	131,252 —	(£5,250.2*s.*)
Signalling staff.	131,664 —	(£5,266.11*s.*)
Train staff	664,560 —	(£26,582.8*s.*)
Cost of traction.	736,436 —	(£29,457.9*s.*)
Cost of lubrication.	26,312 —	(£1,052.10*s.*)
Total. . .	3,371,764 francs	(£134,870.11*s.*)
To this must be added 9 per cent of the pay of the staff, contributed by the company to the pension fund, namely	85,992 francs	(£3,439.14*s.*)
Total working expenses, pensions included . . .	3,457,756 francs	(£138,310.5*s.*)

(1) The cost of staff for lighting and heating the stations is included (for 6,000 francs [£240]) in the ,660 francs (£3,186.8*s.*) given above for the heating and the lighting of the stations.

*

Capital charges.

Assuming that the capital of. . . . . 86,332,700 francs (£3,453,308)
is to be amortized in fifty years, the annual chages corresponding to that capital, assuming a rate of interest of
4 per cent, is. . . . . 4,018.787 — (£160,751.10*s.*)
In this case, the total annual charges amount to. . . 7,476,543 — (£299.061.14*s.*)

The net cost, on these assumptions, then amounts to $\frac{7,476,543}{3,000,000} = 2{\cdot}492$ francs per ton (2*s.* 0·31*d.* per English ton), and to $\frac{2{\cdot}492 \text{ francs}}{260 \text{ kilometres}} = 0{\cdot}0096$ franc per ton-kilometre (0·151*d.* per English ton-mile).

Note by the French Northern Railway on the net cost of carrying coal on a line specially built for the purpose, capital charges included XIII-129

SECTIONAL DISCUSSION

Meeting held on 5 July 1910 (morning).

MR. EVELYN CECIL, VICE-PRESIDENT, IN THE CHAIR.

Mr. Colson. (In French.) — As I am a reporter on the first question which we are going to discuss, I have requested Mr. Cecil, vice-president, kindly to take the chair at this meeting.

The President. (In French.) — I call upon Mr. Louis Marlio, reporter for all countries except America and Great Britain, to give a summary of the report drawn up jointly by him and by Mr. Colson.

Mr. Louis Marlio, *reporter.* (In French.) — In the report which Mr. Colson and I have drawn up, relating to the question of the influence of waterways, considered as feeders and as competitors, on railways, we have divided our statements into three sections :

The first section contains a short review of the countries, England and the United States excepted, where navigation is of importance. In this review, we examine the administrative regime affecting railways and waterways, the importance of the traffic and the cost of carriage by rail and by water.

In the second section, which is the most important one, we consider the different factors which influence the distribution of the traffic between the railways and the waterways.

Finally, in the third section, we try to determine, from information given by many writers, by a method, approximating as nearly as possible to actual practice and based on actual results, the net cost of carriage as compared with that on waterways.

I will give a short summary of these three sections.

In the first place, we have examined the situation on the railways and the waterways in different countries, namely in Russia, Germany, Austria, Hungary, France, Belgium and Holland.

I will at once state that the report was written two years ago; the figures we give are accordingly somewhat old now, particularly those concerning the net profits of railways, which have materially diminished for the last two years in all the countries of the world.

Hence, we must go back two years in order that the statements in the report

*

may be considered as in agreement with truth.

Without entering into the details of this first section, I will give some very striking figures in order to show in what countries a comparison of the relations between railways and waterways may be of most interest.

In the first place, we must mention Russia, for it is in that country where water carriage is of most importance, both from the absolute and from the relative points of view.

From the absolute point of view, the waterway traffic amounted to 35 milliard ton-kilometres (21,404,889,000 English ton-miles). I may here mention that by a printer's error the figure is given as 35 millions, while it should be 35 milliards on page 31 of the report (1).

What is curious is that the ton-mileage of the railways is the same as that of the waterways, and that the growth of the railway traffic is absolutely paralleled by that of the waterway traffic.

After Russia, and leaving out of consideration England and the United States, the country where navigation is of most importance is Germany, where the traffic on waterways amounted in 1905 to 15 milliard ton-kilometres (9,173,524,000 English ton-miles), as against one of 45 milliard ton-kilometres (27,520,571,000 English ton-miles) on railways.

The third place is occupied by France, where the waterway traffic is 5 milliard ton-kilometres (3,057,841,000 English ton-miles), as against a railway traffic of 19 to 20 milliard ton-kilometres (11,619,797,000 to 12,231,365,000 English ton-miles).

As regards the administrative regime of waterways and railways, I will at once draw your attention to the importance of the direct or indirect subventions given to the waterways by the different States.

Generally speaking, while railways have been built by companies, the different governments have as a rule been far more generous towards the waterways which have been constructed at the State's expense.

The principle now accepted in the case of waterways is that of free gift; that is to say, that the capital expended on the construction of waterways is sunk, without return.

We have, however, noted a few exceptions; in France, we can mention the case of the city of Paris, the Marne-Saône canal, where certain tolls are levied. I may add that the yield of these tolls only represents a very small fraction of the capital charges.

In Germany, the principle of charging tolls is more general than in France; it is the ordinary principle on canals and on canalized rivers, such as the Main; it was the principle which was adopted when the 1905 programme was voted, in the case of all the free rivers; but this principle is not yet applied owing to international difficulties which arise in connection with the introduction of tolls on the two great rivers, the Rhine and the Elbe.

The remark we have just made is essential to the question, for in comparing rates, we must remember that railway tariffs always include a fraction towards the maintenance of the line and the amortization of the capital, while this is not the usual practice in the case of waterways.

(1) See *Bulletin of the Railway Congress*, number of March, 1910, p. 1127.

In the second part of our report, we have tried to ascertain and determine as accurately as possible the importance of the different factors which may in one way or another influence the distribution of traffic between railways and waterways.

Before entering into details, we have to remark that waterways, owing to their very position, cannot compete, in all directions, with railways.

On the other hand, it must not be forgotten than waterways can also not compete with railways for all kinds of traffic; passenger traffic and quick-freight traffic must be excepted.

Among the factors which influence the distribution of the traffic, the most important is *the cost of carriage*.

It is self-evident that when we talk of comparing the cost of carriage, we must compare things that are really comparable, and only compare with the freight charged by ships, the railway rates, applicable to goods sent under the same conditions, for instance by train-loads, and when the handling is at the cost of the consignor or the consignee.

Generally, we find that the cost of carriage by water is lower than that by rail; this depends, in most cases, on the absence of tolls on waterways. It must be noted that the cost of water carriage varies greatly, according to the geographical and technical conditions of the different waterways. Moreover, we must not compare the cost of carriage by water and by rail merely on the basis of the rate per ton-kilometre; this does not suffice, for when there is competition between a waterway and a railway the waterway always takes longer; in fact in the latter case gradients must be gentle and opposing gradients have to be avoided, consequently a more or less sinuous route has to be adopted.

It follows that the distance the goods have to travel may be lengthened considerably; on the Seine the waterway is 80 per cent longer than the railway; on the Rhine, it is only 17 per cent longer.

The freight increases rapidly with *the gradient of the waterway*, as any increase in this involves on rivers a large increase in the cost of haulage, and on canals a multiplication in the number of locks, causing much loss of time; the passage of each lock takes, in fact, from twenty minutes to half an hour.

Then also *the size of the boats* has to be taken into consideration. The difference is considerable; thus we have the 60-ton barge on the Berry canal, and then the Flemish 300-ton lighter used in Belgium, in Holland and in the north of France; next we find in Germany 400-ton barges on the Brandenburg canals, and 600-ton barges on other canals. Thus there are the river boats attaining, in Germany, to 600 tons on the Elbe; in France, 1,000 tons on the Seine; 2,000 and 2,500 tons on the Rhine; and finally in Russia, up to 9,000 tons on the Volga.

Finally, we must mention, as a factor exercising considerable influence on the freight, *the method of traction;* this varies from human to animal traction, and to mechanical traction operated by steam and by electricity.

If we take all these factors into consideration, we must conclude that a bad river is worth less than a good canal, where there are not too many locks; and that a good canal is worth infinitely less,

from the point of view of cost, than a good river.

This difference has to be remembered, for as regards rates, the railway easily competes with a bad river, fairly easily with a canal, even a good one, but only with very great difficulty with a free-running river, such as the Rhine and the Volga.

Besides the cost of carriage proper, we must also compare the terminal charges; these are, generally, rather higher with waterways than with railways. This advantage becomes considerable when the manufacturer who utilizes the railway is connected with it by a private siding; the development of private sidings is a very powerful weapon for the railway. We will quote some figures which show the advantage of these sidings to the French Northern and to the French Eastern Railway.

The third factor to consider is *the length of the journey* to be effected.

As regards short distances, we may say that the obtaining of the traffic does not depend on the cost of carriage proper, but on the terminal charges. The traffic will go wholly by that of the two ways, which has the lowest terminal charges or the greatest facility of access.

At medium distances, the competition of waterways makes itself felt; at large distances, it is generally said that the ordinary waterway has a great advantage. That is often true; that is so in Russia where the mean length of journey of rail-borne goods is half that of water-borne goods, and also in Germany, where it is 114 kilometres as against 290 kilometres (71 miles as against 180 miles). In France, on the contrary, the mean length of journey is the same in both cases, namely about 150 kilometres (93 miles).

It must be noted that this advantage of the waterway at long distances is not general, and that it is largely influenced by the rating system adopted by the competing railway. In this respect, there is a very marked difference between France and Germany : in Germany, rates are, generally, made on a fixed basis; in France, on the contrary, on a differential basis, decreasing with the distance; it follows that in France the length of journey at which the waterway competition is most effective is frequently a medium one, while if great, the kilometric basis of the railway tariff becomes less than the kilometric basis of the waterway tariff, so that for distances of more than 600 to 800 kilometres (370 to 500 miles) the advantage is again with the railway.

The next chapter of our report deals with the time required for the journey.

In this case the railway has a marked advantage if we consider the ordinary time the railway takes, and not the legal time specified in the rules which the railway is bound to observe.

In our report we mention instances in which the waterways can carry certain goods almost as quickly as the railway. It is in Germany that these instances are found, owing to the very favourable topographical conditions of these waterways and to the excellent organization of the shipping service from the commercial point of view, as well as from that of fast steam haulage.

A remarkable instance of these quick-freight services is to be found on the Elbe, where there are very well-organized shipping companies running boats at short intervals. In particular they take goods

from the frontier of Bohemia to Hamburg, a distance of about 600 kilometres (373 miles). In France, the average speed of carriage on waterways does not exceed 15 to 20 kilometres (9·3 to 12·5 miles) per day. On the Rhine, the average speed may be estimated at 70 kilometres (43·5 miles) per day, and on the Volga, at 75 kilometres (46·6 miles) per day.

Now what is the influence of *the nature of the goods?* Are there goods specially suitable either for carriage by water or for carriage by rail?

One can mention coal as preferring, at equal rates, the railway, owing to the deterioration it undergoes if carried by water, owing to the damp and to the long time required for the journey; this leads to heating of the coal and to its decomposition.

Messrs. Gruner and Weyhemmayer have given particulars about the deterioration of coal carried by water. This deterioration is a fact, and one which is of great importance to manufacturers; it is of less importance to retail coal dealers, whose customers have no apparatus for determining the number of heat units produced by the combustion of a given weight of coal.

In the case of coke, the deterioration is even more marked than in the case of coal; it is estimated at from 1·50 to 2·50 francs per ton (1*s.* 2·63*d.* to 2*s.* 0·39*d.* per English ton), according to conditions.

The sixth chapter of the second section of the report considers the influence the value of the goods may exercise on any preference to be given to the one or the other means of carriage.

In this connection there is a prejudice which has to be overcome: for forty years it has been repeated that railways are suitable for carrying goods of greater value, while waterways are suitable for carrying goods of less value. That is an error, for boats can take goods of greater value, and railways can take goods of less value. We give instances of this in our report.

As regards goods of a certain value, the disadvantages peculiar to waterways, less security and slower conveyance, are counterbalanced by the fact that on railways goods of greater value are charged higher rates than goods of less value.

In order to make competition possible, however, it is necessary that the speed of the water carriage should be sufficiently great and that the service should be properly organized. This is the case on the Elbe and on the Rhine.

On the other hand, railways do not refrain from carrying goods of little value and there are even railway systems on which heavy goods form the bulk of the traffic. In France, taking all the railways, the heavy goods amount to 70 per cent: on the waterways 25 per cent of the goods are of greater value. As regards coal, if we compare railways with waterways, we find that it forms 28 per cent of the total railway traffic and 32 per cent of the total waterway traffic.

We next examine the habits of the clientele. A fact which has to be remembered is that the waterways, as they carry large consignments at a time, can only appeal to very large business firms or manufacturers, while railways include medium-sized and small firms among their customers.

Waterways can only be used by manufacturers who make large stocks, who ac-

cordingly have large works and a more or less large working capital.

In the eighth chapter of the second section of our report, we note that among all the centres to or from which goods are consigned, it is above all the great centres which most attract waterway traffic. The great centres from which goods are sent by water are in mining or in industrial districts, and the places to which they are sent are generally the large cities, owing to the preponderance of water carriage in the case of building materials and of cereals.

In the ninth chapter of our report, we more especially consider a question of some importance to France and to Germany.

Waterways as compared with railways are far more important from the point of view of imports than from that of exports.

This is due to two causes : firstly, to the favourable conditions under which goods can be transhipped from the cargo-boat to the barges; the goods are generally cereals arriving from America in bulk, and which can be transhipped at once. On the other hand, if it is a question of sending cereals from a country producing them to other countries, the consignments arrive in small lots; consequently, they cannot be transhipped at once, and they must be stored before they are put on board the cargo-boat.

The second reason, and the more important one, is that the railway is hampered by protectionist opinions, in most countries, when it is a question of making tariffs to favour imports.

This fact has been observed very clearly on the Seine; in our report we give curves showing the decreasing or stationary importance of certain railway traffics, and the continual increase of the same traffics on waterways.

This is also marked in the case of Germany, where the cereals traffic on water exceeds 3 million tons, as against only 100,000 tons on the railways.

In the tenth chapter, we examine how the equilibrium between the two systems of carriage, established as just described, becomes disturbed. This equilibrium is not stable; it is influenced by the variations in freight, which goes up when traffic increases and goes down when it decreases, while railway rates remain the same.

Freight is affected by three chief factors, one of which is of a technical character; this is the state of the waterway, as affected by the depth of the water, the current, etc. During each year, the freight varies with the season, with the amount of traffic. Thus in France the freight for carrying coal from the North to Paris goes up in autumn and goes down in spring.

The variations in the economic activity also influence the freight; this is a fact which we have tried to make clear in the table given on page 90 of the report (1).

During boom times the increase of the traffic on railways is always greater than on waterways.

The waterway does not appreciably increase its traffic-capacity during those times, while the railway, which is compelled to carry, increases its traffic-capacity, and hence takes a greater proportion of the traffic.

It would seem that the inverse pheno-

(1) See also *Bulletin of the Railway Congress*, number of March, 1910, p. 1186.

menon should be produced during times of slump, but we have not found any evidence to establish this; it is found, in most cases, that the losses on waterways are neither larger nor smaller than those on railways. This may be explained by the fact that the carriage of articles of food, which forms an important fraction of the railway traffic, is not influenced by economic crises, and, moreover, the railways cater for nearly all the smaller firms. Now the effects of economic crises only make themselves felt at a subsequent period in the case of smaller firms, while it affects big firms almost at once.

We now come to the eleventh chapter of the report, dealing with the measures taken by the railways to fight the competition of waterways.

This competition can be direct when the railway carries the goods from end to end. It is often hampered by administrative regulations which, except in Hungary, in Austria and in Russia, trammel the freedom of the railways as regards the modification of the rates. These regulations are rather severe in France; we give, on pages 96 and 97 of our report (1), instances which show that in some cases at least the railway is completely beaten by the waterway.

The competition can also be indirect, that is to say, it can be against mixed traffic, that is to say, in case the waterway is used for part of the journey and the railway for the other part. The railway can then proceed in two different ways, either reduce the size of the zone for which mixed carriage is cheaper than direct railway carriage (this is done in Germany along the Rhine and the Elbe), or when mixed carriage cannot be avoided, arrange matters so that the route taken is such that the rail journey is a maximum.

We give an instance of such indirect competition, in particular in Russia, where tariffs are arranged to retain the traffic between the Volga and Moscow and St. Petersburg on the railway for as long a distance as possible. In Germany, this competition takes the form of exceedingly low rates for the coal and minerals carried on the Rhine, the Elbe and the Oder.

We now come to the third section of our work, in which we have tried to determine what the net cost of carriage by rail may be, in the case of goods of the kind carried on waterways.

The net cost of carriage on waterways is very easy to ascertain, as owing to the competition existing between small boats, it may be assumed, without fear of error, that the net cost of water carriage approximates to the mean freight, which covers the cost of traction, the amortization of the boat, and the ordinary pay of the boatman, considered as a workman.

On railways, that is not the case; we consider in the first place the case where there is competition between a waterway and an existing railway, and we estimate the extra cost incurred in order to run an additional train.

Assisted by investigations made and brought to our notice by several French railways, especially the French Eastern, we found this to be 0·65 centime per ton-kilometre (0·102*d.* per English ton-mile).

(1) See also *Bulletin of the Railway Congress*, number of March, 1910, pp. 1192 and 1193.

This figure only includes the expenses special to the train, the cost of coal and oil, the interest and amortization of the locomotives, the pay of the drivers, firemen and other train men; these are specialized expenses and it would be a mistake to think that the figure so obtained by us represents the net cost. It is much too small.

In order to allow for miscellaneous expenses, we have taken the average for the French railways, and this is certainly too much.

As for the expenses of the traffic service, these are very small if we deduct the expenditure on train men, included among the specialized expenses; in order to allow for them, we have added 0·20 centime per ton-kilometre (0·031*d.* per English ton-mile).

Finally we have to consider the cost of the additional works made necessary by the growth of the traffic. We have made the calculations for this growth for the last twenty years on the French Northern and the French Eastern, and this calculation has given the figure of 0·34 centime (0·053*d.* per English ton-mile) which has been added to the previous amount.

Thus we obtain a total of 1·19 to 1·20 centimes, which may be considered the net cost of carriage of a ton of coal or of mineral per kilometre (0·187*d.* to 0·188*d.* per English ton-mile).

In the second example, we have taken the case where it is necessary to build a railway. The French Northern Railway has supplied us with particulars of a calculation showing the net cost, and this does not exceed 1·20 centimes per ton-kilometre (0·188*d.* per English ton-mile).

Our conclusion is as follows : we arrive at the same result as before, that is to say, that the net cost of carriage of goods similar to those carried on waterways, can be estimated at between 1 and 1·20 centimes per ton-kilometre (between 0·157*d.* and 0·188*d.* per English ton-mile) on railways.

This cost is less than the freight on average and mediocre waterways, especially if we allow for tolls; but it is appreciably greater than the freight on large rivers, such as the Rhine and the Volga.

It can hence be concluded that railways can nearly everywhere compete advantageously with waterways if these had to pay for their maintenance.

The only exception is in the case of large rivers with small fall, on which it is possible to carry goods in large lots. (*Applause.*)

Mr. Jebb, *reporter for Great Britain.* — Mr. President and Gentlemen, I must apologise for speaking in English but you will all, I am sure, be relieved to hear that I intend to occupy only a very few minutes giving you an abstract of the short paper I have written on the subject which has been referred to me, *viz.* :

" The investigation of the influence of waterways considered as feeders and as competitors on Railways " in Great Britain, her colonies and India.

After giving the subject my best consideration and carefully analysing the replies which were sent by the railway companies to questions I submitted to them I have come to the following conclusions :

I. *Great Britain and Ireland.* — That the influence of waterways, considered as *feedeers*, on railways is negligible, except

in the case of the Birmingham Canal Navigations. This canal system is in many respects unique; it forms a network of canals in the mining district of South Staffordshire, is 159 miles in length and there are some 500 private branches or basins connected with it.

Works of almost all descriptions have, from time to time, been built on the banks of the canal and many of these works have no direct communication with the railways.

Three of the great Railway Companies — the London & North Western, the Great Western and the Midland — whose lines intersect the district, have therefore constructed transhipping basins and depots at many convenient points and made branch railways to them; traffic is brought by boat from works to these basins and put on the railway The Birmingham canal may therefore be considered as a useful feeder to the railways.

The total amount of traffic (it is chiefiy from canal to railway) interchanged at these depots is about 1,200,000 tons per annum (the annual traffic on the canal being about 8 million tons). Of the forty-one railway companies in the United Kingdom of Great Britain and Ireland, about one sixth of them have waterways to compete with — details of these are given in my report.

The competition of the waterways is in some districts considerable, but it does not appear, at the present time to be either increasing or diminishing to any material extent.

It is probably less than it was thirty or forty years ago : there is, however, one exception *viz.* : that of the Manchester ship canal.

This canal is 35 $^1/_2$ miles in length and was opened for traffic in 1894 — it begins at Eastham near Liverpool and ends at Manchester. Large docks and quays have been constructed at Manchester for the accommodation of the largest cargo-carrying vessels and extensive warehouses have been built.

The effect of this canal, as a competitor with railways, is that oversea traffic which, if the canal had not been made, would have been landed at Liverpool, Birkenhead or other ports, thereby giving the railway companies the carriage to Manchester and other towns, is now delivered at Manchester by ocean going vessels. The amount of traffic so diverted is considerable.

Sea competition is very effective and most of the great railways are affected by it — traffic is conveyed between nearly all ports by coasting services.

The Royal Commission on Canals and Waterways to which I have referred in my paper has now reported. There were nineteen members of the Commission — sixteen have signed the majority report, but of these, four dissent in strong terms from their recommendations, a fifth makes independent reservations, while three have not signed at all but made separate reports in which they severely criticise and condemn the majority report.

The majority report recommends the formation of " a Waterway Board " to " review the whole situation on the lines of practical business " and " if satisfied " that the improvement of the canals between Birmingham and the ports of Liverpool, Hull, London and Bristol would be desirable, to propose a scheme for submission to Parliament.

The majority report is in favour of pub-

lic money — about £17,500,000 — being provided for the improvement of these canals.

Many of those who have most carefully considered the question are of opinion that a very much larger sum would be required to make these new canals and that if they were made, they would not pay the cost of maintenance. The witnesses who gave evidence in favour of improving the canals made it quite clear that the public could not be depended upon to find any money, and it was evident that the chief object of the witnesses was to bring down railway rates.

II. *India and Colonies.* — The waterways as they now exist interfere only to a slight extent with the earnings of the railways. Some interesting particulars have been supplied by the railway companies which have been embodied in my report.

The President. (In French.) — The reporter for America being absent, I will request Mr. Colson kindly to give us a summary of Mr. William Hoyt's report.

Mr. Colson. (In French.) — Mr. Hoyt's report deals with the question of waterways in America.

Towards the middle of last century many canals were built, most of them by companies. When the railways began to develop, the companies gave up nearly all those canals, as they were no longer of any real use for points where railway communications exist. Thus 2,444 miles of canals, which had originally cost over £16,000,000, were simply and purely abandoned. One of the canals belonging to the State of New York had been of considerable importance, namely the Erie canal.

The United States are richly endowed with natural waterways. But the traffic on these ways has become very small, even on the Mississippi; at St. Louis shipments which amounted in 1890 to 600,000 tons, now only amount to 89,000 tons. The only important traffic which still exists is on the Ohio, chiefly coal from Pittsburgh.

The United States have, on the other hand, an incomparable system of inland navigation, namely the great lakes, where the conditions are such as to defy any railway competition. But this is a very special case, approximating much more to ocean navigation. The traffic has developed to an extraordinary extent.

In the United States, as in Europe, generally, the government is trying to stimulate inland navigation; the State of New York is enlarging the Erie canal: it does not hesitate to incur an expenditure of over £20,000,000 in order to make this canal accessible to boats drawing 3·50 metres (11 ft. 6 in.) of water. The federal government has been investigating a very vast scheme for improving the waterways, a scheme which has not yet been sanctioned by the legislature.

Mr. Merczyng, Russian State Railway. (In French.) — Gentlemen, you will allow me to add a few words.

It is a question of a technical development which in the near future will exercise great influence; I mean mechanical traction and more especially electric traction on waterways.

At present, except in the North of France and in Germany, no large enterprises of this kind are yet to be found; but in Russia schemes are being prepared for

our large canal systems, especially those around lake Ladoga.

It is proposed to develop mechanical traction by utilizing the water-powers.

Thanks to the progress of electro-technics, we shall see the waterways operated like railways, and as on railways, services of trains of boats running at fixed hours will be organized on those waterways.

There is already a fixed time-table on the Brussels-Mons canal in Belgium, and we shall soon see the traction monopolized by great companies or by the State, and rates made according to the value of the goods carried and the liability incurred, just as in the case of railways.

From this time onwards, the equilibrium between the railways and the waterways will be completely modified.

Such is the future.

At a future session of the Congress, I think that we shall bring forward information which will entirely change the aspect of the question.

Mr. Timonoff, ministry of ways of communication, Russia. (In French.) — I will begin by paying my respects to our reporters; the reports which you have had an opportunity to read, on the question of the influence of waterways on railway traffic, are really very able.

If you consider the difficulties of combining all the constituent parts of those reports, you will recognize the great work done.

Messrs. Colson and Marlio's report, which contains so many statistics and to which so many tables are annexed, has certainly involved weeks and even months of correspondence and of work in order to be completed, so as to be submitted to the Congress.

Anybody who would try to criticize these labours would certainly have a thankless task.

That being said, I ask permission to add some new information to that supplied to you, concerning the waterways in Russia, and to give you some particulars which you will perhaps find of interest.

It has to be noted that matters have gone on in the same way in Russia as in England and the United States of North America, as already mentioned.

In accordance with the wishes expressed by the Russian parliament, the State Duma, the ministry of the ways of communication appointed a commission for investigating the question of waterways. This commission is intended to examine all the points bearing on the question of the importance of waterways compared with that of railways.

This commission, which by now has been at work for several months, has found that the time had not yet arrived for generalizing the question of competition of railways and waterways.

It is impossible to lay down as a general principle whether railways should be built or waterways constructed; in every country and in every district, this is a question of kind.

The general opinion expressed in the reports which are before you, is in favour of railways: but reservations have just been made in the case of the great lakes in North America, and also in the case of the Manchester ship canal. That could also be done in other cases.

The Volga has been mentioned, and it

has been stated that that was a river along which there was no railway.

Those are questions of kind, and it is advisable to continue their investigation, for the time has not yet come for drawing possible conclusions about the influence of the competition between railways and waterways.

I observe that at the Railway Congress there is naturally a certain bias in favour of railways; but I have also been present when the Inland Navigation Congress discussed the same question, and there the bias was in the opposite direction.

In 1910, we are in a better position to discuss the question. Yesterday, at the opening meeting, we were reminded of the history of the work of the Congress during twenty-five years, and of the wonderful way in which this organization labours and investigates, but it has not been mentioned that the Railway Congress has given rise to analogous institutions in other branches of industry. Thus there is at present a Permanent Commission of the Inland Navigation Congress, a commission which meets at the same city as the Commission of the Railway Congress, and thus there is perhaps a possibility of thorough investigation, which could be undertaken by the bodies working jointly, and which would probably be richer in results than any which each of these congresses could obtain separately.

These are the considerations which lead me to think that we should not adopt too definite conclusions at the present session, for this is a question of kind, not only in the different countries, but also in the different districts of one and the same country.

There is a whole series of important investigations which have to be made.

These investigations could be made under more satisfactory conditions if a proper programme were to be drawn up jointly by the Commission of the Railway Congress and by the Commission of the Inland Navigation Congress, a programme which would include all the points necessary, and would be sent to all the members of both permanent commissions.

Under those conditions, we could then at the next Congress have a report which would perhaps lead us to more definite conclusions.

Therefore I have the honour of submitting to you the following resolution :

" It is desirable that in all countries where inland navigation plays or can play an important part, the study of the reciprocal influence of waterway and railway carriage should be carried out in a continuous and systematic manner, in accordance with a programme drawn up by the Permanent Commission of the Railway Congress, acting conjointly with the Permanent Commission of the Navigation Congress."

Mr. Riché, French Eastern Railway. (In French.) — I should like to make two short observations to you in connection with the proposition which has just been made of making a sort of agreement between the Railway Congress and the Navigation Congress.

The first is purely a matter of form. It seems difficult, considering the Constitution of the Railway Congress, which defines its object and scope, that we should vote for the principle of making an agreement with another association which has

its own individuality and which must follow its own road.

The programme which could be drawn up, conjointly, would only be theoretical, for there will always be a profound difference between the organization of railways and the organization of canals. That difference has been set forth very clearly in Mr. Colson's report : in the one case the cost of construction of the canals, of their maintenance, of their amortization, is not allowed for, while in the case of railways this cost is included in the working expenses, and the capital becomes amortized.

If a joint programme were to be drawn up, ways and means of carrying out this programme would still remain to be found.

Would the companies be authorized to make competitive tariffs? I do not think so, at least not as far as France is concerned.

On the other hand, it would be necessary to have homogeneous shipping rates and a combination of companies organizing a joint system.

At present shipping is very scattered; there are very many small ship-owners, who make a poor living, but who have not even enough capital for their own purposes, so that they are obliged to borrow money at high rates in order to make it possible for them to carry on their business, to pay and feed their men.

It seems very difficult to organize the shipping services so as to form a general combination, which until now has never existed. It has never existed because there are shipowners, but no shipping services, above all in France, where neither a joint organization nor common rules are in existence.

There are in fact great difficulties in organizing and operating shipping.

Mention has been made of modifying the conditions of carriage, of improving them, by applying electric or mechanical traction. It is evident that under those conditions, it would become easier to compare the two methods of conveyance, waterways and railways, but at present we, the Railway Congress, must limit ourselves to recording that in the present state of affairs there are such profound differences between waterways and railways, that no comparison can be made, and that we must allow for differences of kind, not only from country to country but also from district to district.

Mr. Franke, Prussian State Railway. (In German.) — I equally hesitate to accept the proposal brought forward by Mr. Timonoff, and my objections are of the same order as those brought forward by Mr. Riché in the second part of his speech. I am also of opinion that the Congress must be content with recording that owing to the difficulties and differences which exist in different contries, it is difficult to make a uniform comparison. The report drawn up by the reporter shows in fact that conditions vary so much from country to country that it is impossible to find terms of comparison for any uniform statistics, and very difficult to come to an agreement about this with the Inland Navigation Congress.

This is how we proceed in Germany : we deliberately avoid all competition with waterways. The State which constructs and operates the railways also constructs

the canals and improves the rivers. It knows that these waterways cannot yield the same return as the railways. Nevertheless it constructs them because it knows that countries, and especially our German countries, have an urgent need of both of these systems of conveyance, waterways and railways. Statistics of this kind would hence not be of much use. Accordingly my chief objection to the proposed resolution is that conditions vary so much from country to country that it is difficult to find any good basis for the comparison.

Mr. Colson, *reporter*. (In French.) — We have drawn up conclusions summarizing the statements contained in the reports. In accordance with the custom of the Railway Congress, these conclusions are not directed towards proposing any measures which should be applied, but limit themselves to recording the results of the reports and of the discussion.

Before reading out these conclusions to you, I should like to say that I will very willingly support Mr. Timonoff's resolution. I will add, in this connection, that I think that Mr. Riché believes this resolution to be much more comprehensive than it really is. Mr. Timonoff does not ask for an agreement between the Railway Congress and the Inland Navigation Congress as to the relations between the two systems of conveyance, an agreement very difficult to realize. What he asks for, is an agreement as to the method of investigating the comparative advantages of the two systems of conveyance. The measures to be taken in order to make this investigation effective, while taking both sides of the question, will be arranged by joint agreement of our Congress and the Navigation Congress. That is a desire which I share. I have been present at navigation congresses and I have tried to have this point discussed. I think that the railways have very much to gain if during a joint discussion, the partisans of navigation are placed in a position to explain how and why they think their waterways superior to railways. I think that railways would certainly benefit enormously by this, in public opinion.

Hence I support Mr. Timonoff's resolution. That being said, these are the conclusions submitted to the meeting for approval. They are somewhat long, but if we only state that we consider our system better than the competing system, without explaining why, we do not say much.

" The Congress notes that waterways as a rule play a much more important part as competitors than as feeders of railways. The factors which influence the division of the traffic between the two ways are as follows :

" 1° *Rates*, which are generally lower by water than by rail; this is more especially due to the fact that railway rates are fixed so as to remunerate the capital spent on construction as much as possible; on the other hand, as regards waterways, States sometimes supply capital and attend to the maintenance without remuneration, or else are satisfied with collecting tolls which only exceptionally cover the cost of maintenance; only in England is the contrary the case, and there inland water carriage over long distances has become very rare. In spite of the advantage granted everywhere else to their competitors, railways, when free to modify their rates for

the traffic which is competed for, without granting other classes of traffic reductions in rates incompatible with the charges incurred, can easily lower their rates without losing all their profit, and make cheaper rates than those obtainable on smaller waterways, with many locks and numerous curves. Only with difficulty do they reduce their rates to the level of the freights charged on large rivers with a gentle gradient, well regulated and provided with the necessary equipment, as in the case of the Rhine and the Volga; and their rates always remain higher than the freight on the great lakes which are similar to inland seas;

" 2° *Terminal charges*, which have a notable influence on the choice between the two ways, when only one of them is in direct connection with the establishments of the consignors or the consignees, either because these are located on the banks of the waterways, or because a private siding connects them with the railway. This factor is decisive in the case of short distances; competition begins at medium distances, and the railway gains or loses influence, as the distances increases, according to whether the tariff is a differential one, or whether on the contrary it remains practically proportional to the distance;

" 3° *The time required for the journey*, which is much less on the railway, except in the case of relations where the economical and geographical situation of the waterway makes it possible to use powerful steam-engines; on the other hand, water-carriage is nearly everywhere subject to interruptions which do not affect railways;

" 4° *The nature of the goods*, which resist more or less well the effects of water-carriage. It is by no means correct (as is often said) that the line of separation is formed by the value; water-carriage is used for goods of a rather considerable value per ton, when technical and commercial conditions make a regular service possible; its disadvantages are then counterbalanced by the relatively high rate which railways charge for such goods; railways, on the other hand, can carry large consignments of heavy goods at as cheap a rate as the waterway, on lines of easy profile serving the same relations. The objections to the longer time required for the journey, and to the effects of damp, may be as important for low-price goods (coal) as for more valuable articles;

" 5° *Direction of traffic at seaports.* — Waterways take away from railways a larger fraction of the import traffic than of the export traffic, especially while regulations and public opinion prevent railways from applying the same reduced rates to imports as to exports and also because direct transhipment from ship to lighter is easier for oversea goods carried in large quantities by sea than for home produce which generally arrives in small quantities from various parts of the country, to be shipped when a ship is available;

" 6° *Variations in the activity of the traffic*, due to the season or to economical crises. The railway has much more flexibility in meeting sudden changes. Variations in the activity of business produce, in the case of railways, large variations in the amount of traffic offered; these only in very exceptional cases cause alterations in the rates. On the other hand, the waterways retain a less variable tonnage of the traffic competed for, by raising or

lowering their rates according to the state of the market.

" Next considering the position of waterways as feeders of railways, one sees that if the latter were able to modify their rates at their own convenience, they would nearly always be able to carry consignments the whole way, giving the public as favourable conditions as mixed carriage would, while at the same time realizing a higher profit to remunerate their capital.

" A railway administration has not much interest in cooperating with inland waterway services (unless these are of a quasi-marine character) except in three cases :

" *a*) When railways are prohibited from making lower rates so as to retain the traffic for the whole distance, as is generally the case with imports;

" *b*) When their lines are able either to receive from waterways or to bring to them traffic which might be carried the whole distance by a rival railway;

" *c*) When in a country where the railway system does not yet provide for all important currents of traffic, as in Russia, the State was wise enough to connect first by means of railways the centres not already connected by waterways, so that a mixed route is the only one possible for many articles.

" If it is necessary to establish a new line to provide for a considerable flow of traffic, for which existing lines do not suffice, and if the topographical and economic conditions would make an artificial waterway possible, the same result can be obtained with less expenditure, by constructing a railway."

Additional clause proposed by Mr. Timonoff and accepted by the reporters :

" It is desirable that in all countries where inland navigation plays or can play an important part, the study of the reciprocal influence of waterway and railway carriage should be carried out in a continuous and systematic manner, in accordance with a programme drawn up by the Permanent Commission of the Railway Congress, acting conjointly with the Permanent Commission of the Navigation Congress."

I think it is advisable not to decide today about these conclusions, but to wait until they have been printed in the *Journal quotidien de la session* so that each of us can examine them at leisure. We could again consider the subject at our meeting tomorrow afternoon. (*Signs of approval.*)

The President. (In French.) — This proposal seems to meet with approval. That shall accordingly be done.

Meeting held 6 July, 1910 (afternoon).

The President. (In French.) — Before discussing the proposed conclusions, I call upon Mr. Hale to address the meeting.

Mr. Hale, American Railway Association. — I hope Mr. Colson 's conclusions will be passed by the Congress. I draw special attention to the sixth paragraph on

the variation in the amount of traffic offered, and the importance of an understanding by the public of this phase of the question. It is true that railroad service is more elastic than service by waterway, but too often a stoppage of water service throws business suddenly to the railways which they cannot justly be expected to carry, and curiously enough *their efforts to serve the public on such occasions are seldom appreciated.*

I believe that the most important conclusion stated was that under ordinary circumstances a railroad is cheaper to build and maintain than a canal especially as the statement was thoroughly proved by Mr. Colson.

Mr. Hoyt, *reporter.* — The United States National Waterways Commission in its report recently issued says :

> The average European freight rates on railways paralleling water routes are higher than those on lines similarly situated in the United States, and European rates for water-borne carriage, in some instances, even where the traffic is very large, are as high or higher than on railways in the United States where traffic is likewise large.

Evidence of the truth of this is found in a comparison of our United States railway rates with those of Europe.

In Germany, the average railway rate per ton-mile is 13 mills, in France, it is 14 mills, in Belgium, it is between 16 and 17 mills.

In the United States, our average rail rate is only 7·54 mills per ton-mile, or 58 per cent of what it is in Germany, 54 per cent of what it is in France and 47 per cent of what it is in Belgium.

And if we look a little further, we shall see that our railway rates in the United States compare very favourably with European water rates.

On the River Rhone in France, the highest rate is 15·6 mills per ton-mile, and the *lowest* is 7·8 mills, which is higher even than our United States average rail rate.

Then on the Seine, we find the figures running from 26 mills to 56 mills, — the last, seven times greater than our United States average railroad rates.

But, taking an average of all the waterways of France, the rate is not less than 6 mills, and in Belgium, it is approximately 6·5 mills; these figures being based on the actual length of haul.

It was pointed out, however, by Messrs. Colson and Marlio in their report, that waterways are of necessity considerably longer than competing railways in the same territory, and if we take this fact into account, and compute the rates on a basis of distances by rail, we shall find the average water rate in Germany to be approximately 6·5 mills, and those in France and Belgium are 8 mills; the last being somewhat higher even than the United States average rail rate.

This figure of 7·54 mills, it must be remembered, is by no means as low as that on some of our representative American roads handling a large traffic.

In 1907, the average rate per ton-mile on the New York Central was 6·4 mills; on the Pennsylvania, it was 6·3 mills; on the Illinois Central, 5·8 mills; on the Lake Shore and Michigan Southern, 5·27 mills; on the Big Four, 5 mills; on the Norfolk & Wertern, 4·95 mills, and on the Chesapeake & Ohio, 4·33 mills.

*

It would seem therefore that conditions in the United States are radically different from those in Europe as regards competitive rates on railroads and waterways, and that specific conclusions based on experience here will not apply to the United States.

Mr. Haines, United States Government. — The first paragraph of this report maintains the general proposition that navigable routes play a much more important part as competitors to railways than as feeders. This general proposition is however restricted by the exception thereto attached, that " in America, experience proves that competition by canals may not be serious".

It would seem to be useful, in this connection, to recall something of the history of transportation in the United States. At one time, the system of canals in that country promised to be one of the most important in the world. General Washington was perhaps the first to appreciate the value of artificial waterways in opening up to settlement the country which extended westward of the Alleghany mountains. He interested himself personally in the improvement of the navigation of the Upper Potomac river, as part of a system of water and land transportation connecting the waters of the Chesapeake bay with those of the Ohio river; and this undertaking was the forerunner of the Chesapeake & Ohio Canal. He also pointed out the part which the navigation of the chain of great lakes, Ontario, Erie, Huron, Michigan and Superior, was destined to play in the spread of civilization westward. He indicated the site of the present city of Detroit as the point at which the traffic upon these lakes must converge, and referred particularly to the advantages for the location of a canal which were offered through the country south of lake Ontaria, from lake Erie at Buffalo, and along the Mohawk river to the navigable waters of the Hudson river near Albany. He even glanced at the possibility of an artificial waterway to connect Upper Lake Huron with the Ottawa river and Montreal.

The project of a canal between Buffalo and Albany, outlined by the prophetic genius of Washington, was realized in the construction of the Erie Canal, commenced in 1817 and completed in 1825. The completion of this work aroused a general interest in canal construction. The region of Lower Canada was brought into closer commercial relation with the United States by a canal which connected the waters of lakes George and Champlain with the Hudson river. The facilities afforded by the Erie Canal for reaching the vast territory tributary to the great lakes, laid the foundation for the subsequent commercial preeminence of the city of New York, and aroused a spirit of emulation among the merchants of Baltimore and of Philadelphia, who had hitherto enjoyed a virtual monopoly of the trade between the Atlantic coast and the region between the Ohio river and the great lakes. The Chesapeake & Ohio Canal was projected as a substitute for the improvement of the Upper Potomac river, in the interest of the city of Baltimore, and the State of Pennsylvania was induced by the citizens of Philadelphia to undertake the construction of a system of transportation, partly by canals and partly by the improvement of available watercourses, connected by

inclined planes over the intervening mountains, which brought the waters of Delaware bay into direct connection with the Ohio river. The topography of the region between the great lakes and the Ohio and the Mississippi rivers, facilitated the construction of artificial waterways which connected these two great systems of navigation; and by 1835 there was a canal mileage of 2,617 miles in operation in the United States, of which the greater part was devoted to the traffic of the trans-Alleghany region.

In the competition for this traffic, the commercial prosperity of Baltimore was threatened, by reason of its unfavourable position as to communication by artificial waterways with the Ohio river. In this dilemma, attention was drawn to the new method of the iron way which was then being developed in England. In 1827, the merchants of Baltimore projected a railway to Wheeling on the Ohio river, a distance of 378 miles, at a time when there was no other railway in existence over fifty miles in length; and two years before Stephenson had built the locomotive *Rocket* for the Liverpool & Manchester Railway Company.

What has been the result of the ensuing competition between the canal and railroad systems extending across the mountain ranges which form a barrier between the Atlantic coast and the territory extending illimitably westward; a region already favoured by Nature with such navigable routes as the great lakes and the St. Lawrence river on its northern boundary and the internal Mississippi river system to the gulf of Mexico? Railways were no longer projected with the idea of facilitating communication between water routes, but to compete with them. They paralleled the canals and the rivers so effectually that commerce forsook them. It is estimated that a canal mileage of four thousand miles, costing $150,000,000, has been rendered useless by railway competition. The steamboat service on the Ohio and the Mississippi rivers, that had built up the cities of Cincinnati, St. Louis and New Orleans, could not successfully maintain a rivalry with the new mode of transportation; and these cities were compelled to invite railway communication in order to retain their commercial relations, The artificial waterways have been substantially abandoned in the coal regions of the Atlantic seaboard and in the territory between the great lakes and the Ohio and the Mississippi rivers. Even the tide of commerce which had so long pulsated in full current through the Erie canal has diminished to a sluggish stream. Little is left of the once vast commerce on the Mississippi river, save the long-distance traffic in bituminous coal for which the railroad managements do not compete.

The remaining domestic traffic that is waterborne is now held in bondage to the railways. The grain trade continues on the great lakes, in connection with the rail routes from the lake ports to the sea coast, until the close of navigation in winter permits the application af all-rail rates. A vast commerce is still conducted on these inland seas in iron ore, which is transformed at the lake ports into products that cau be more profitably transported by rail. The steamships engaged in the coastwise traffic are in alliance with the rail lines extending into the interior; and even the traffic over the isthmus of Panama is controlled in the interests

of trans-continental railway corporations.

Such has been the outcome of about eighty years of competition between waterways and railways in the United States. But popular opinion is being aroused in behalf of improved waterways and it has procured the political and financial support of the governments of several of the States in the Union and of the federal government as well. The State of New York is endeavouring to restore the usefulness of the Erie Canal by enlarging its dimensions at an estimated cost of over $100,000,000; the federal government has made still larger appropriations for deepening and maintaining the navigable channels of the Mississippi river system; a movement is on foot to connect and utilize the succession of bays, gulfs and sounds that borders the Atlantic sea coast; the Canadians are facilitating the navigation of the great lakes and of the St. Lawrence river so effectually as to deprive the city of New York of its preeminence in the export grain trade; and the far-reaching effect of the proximate completion of the Panama canal is as yet not fully comprehended.

But all these efforts at improvement of the natural and the artificial waterways of the United States will not make them efficient competitors of its railroad system. That system has superseded them because it provides a speedier, cheaper and more convenient mode of transportation; one with less interruption between the ultimate producer and the ultimate consumer. At present, it requires eight days to accomplish a voyage by water between Buffalo and New York. A merchant in the latter city may order from Buffalo by telegraph a trainload of fifty cars, each of thirty tons of grain, and receive it within thirty hours on floats alongside a trans-Atlantic steamship, and at a freight charge which has been for years so low that the Erie canal has ceased to be a competitor for this traffic.

Where competition by rail routes is available, artificial waterways are no longer desired. Their field of usefulness is restricted to regions isolated from railroad communication by sparseness of population and by scanty resources for producing traffic. Artificial waterways provided for regions so situated cannot even be maintained by the revenue from their use. They can only exist as a permanent charge upon the public treasury for the benefit of the few who profit by them.

The President. (In French.) — I will request Mr. Colson to read out the proposed conclusions and as there are amendments, I propose to take them clause by clause. If any members have further amendments to propose I request them to let me have them at once.

Mr. Colson. (In French.) — I think that what was said a little while ago should not result in any modification of the proposed conclusions. The opinion has been expressed that in America the canals have not been able to stand the railway competition. While fully admitting this to be the case, it is none the less true that the waterways are sometimes competitors of railways.

These are the conclusions which are put to the vote :

" The Congress notes that waterways as a rule play a much more important part as competitors than as feeders of railways. "

" The factors which influence the division of the traffic between the two ways are as follows..."

Mr. Fairfax Harrison proposes to insert, after the words " feeders of railways ", the words " in the United States, however, experience proves that canal competition cannot be serious ".

I see no objection to the adoption of this addition.

If there are no further remarks, the first paragraph, as amended, will then run as follows :

" The Congress notes that waterways as a rule play a much more important part as competitors than as feeders of railways; in the United States, however, experience proves that canal competition cannot be serious. The factors which influence the division of the traffic between the two ways are as follows..."

— This first paragraph is adopted.

Mr. Colson. (In French.) — The second paragraph of the conclusions runs as follows :

" 1° *Rates*, which are, generally, lower by water than by rail; this is more especially due to the fact that railway rates are fixed so as to remunerate the capital spent on construction as much as possible; on the other hand, as regards waterways, States sometimes supply capital and attend to the maintenance without remuneration, or else are satisfied with collecting tolls which only exceptionally cover the cost of maintenance; only in England is the contrary the case, and there inland water carriage over long distances has become very rare. In spite of the advantage granted everywhere else to their competitors, railways, when free to modify their rates for the traffic which is competed for, without granting other classes of traffic reductions in rates incompatible with the charges incurred, can easily lower their rates without losing all their profit, and make cheaper rates than those obtainable on smaller waterways, with many locks and numerous curves. Only with difficulty do they reduce their rates to the level of the freights charged on large rivers with a gentle gradient, well regulated and provided with the necessary equipment, as in the case of the Rhine and the Volga; and their rates always remain higher than the freight on the great lakes which are similar to inland seas."

— Adopted.

" 2° *Terminal charges*, which have a notable influence on the choice between the two ways, when only one of them is in direct connection with the establishments of the consignors or the consignees, either because these are located on the banks of the waterways, or because a private siding connects them with the railway. This factor is decisive in the case of short distances; competition begins at medium distances, and the railway gains or loses influence, as the distance increases, according to whether the tariff is a differential one, or whether on the contrary it remains practically proportional to the distance."

— Adopted.

" 3° *The time required for the journey*, which is much less on the railway, except in the case of relations where the econom-

ical and geographical situation of the waterway makes it possible to use powerful steam-engines; on the other hand, water-carriage is nearly everywhere subject to interruptions which do not affect railways."

— Adopted.

" 4° *The nature of the goods*, which resist more or less well the effects of water-carriage. It is by no means correct (as is often said) that the line of separation is formed by the value; water-carriage is used for goods of a rather considerable value per ton, when technical and commercial conditions make a regular service possible; its disadvantages are then counter-balanced by the relatively high rate which railways charge for such goods; railways, on the other hand, can carry large consignments of heavy goods at as cheap a rate as the waterway, on lines of easy profile serving the same relations. The objections to the longer time required for the journey, and to the effects of damp, may be as important for low-price goods (coal) as for more valuable articles."

— Adopted.

" 5° *Direction of traffic at seaports.* — Waterways take away from railways a larger fraction of the import traffic than of the export traffic, especially while regulations and public opinion prevent railways from applying the same reduced rates to imports as to exports and also because direct transhipment from ship to lighter is easier for oversea goods carried in large quantities by sea than for home produce which generally arrives in small quantities from various parts of the country, to be shipped when a ship is available."

" 6° *Variations in the activity of the traffic*, due to the season or to economical crises. The railway has much more flexibility in meeting sudden changes. Variations in the activity of business produce, in the case of railways, large variations in the amount of traffic offered; these only in very exceptional cases cause alterations in the rates. On the other hand, the waterways retain a less variable tonnage of the traffic competed for, by raising or lowering their rates according to the state of the market.

" Next considering the position of waterways as feeders of railways, one sees that if the latter were able to modify their rates at their own convenience, they would nearly always be able to carry consignments the whole way, giving the public as favourable conditions as mixed carriage would, while at the same time realizing a higher profit to remunerate their capital.

" A railway administration has not much interest in cooperating with inland waterway services (unless these are of a quasi-marine character) except in three cases :

" 1° When railways are prohibited from making lower rates so as to retain the traffic for the whole distance, as is, generally, the case with imports;

" 2° When their lines are able either to receive from waterways or to bring to them traffic which might be carried the whole distance by a rival railway;

" 3° When in a country where the railway system does not yet provide for all

important currents of traffic, as in Russia, the State was wise enough to connect first by means of railways the centres not already connected by waterways, so that a mixed route is the only one possible for many articles.

" If it is necessary to establish a new line to provide for a considerable flow of traffic, for which existing lines do not suffice, and if the topographical and economic conditions would make an artificial waterway possible, the same result can be obtained with less expenditure by constructing a railway."

Mr. Franke. (In German.) — I propose a slight alteration at the end of the last paragraph, in order to make full allowances for peculiarities resulting from local conditions. The wording proposed is the same up to the words " the same result ", and then the continuation should be replaced by " can be obtained by constructing a railway, costing less for construction and operation; particular cases being of course excepted."

Mr. Colson. (In French.) — We have no objection to the proposed addition; we have taken care, while recording the technical superiority of railways as a rule, to mention that there are special cases where navigation can encounter specially favourable conditions which will make it cheaper.

— The conclusions, with the amendment proposed by Mr. Franke, are adopted.

Mr. Colson. (In French.) — There still remains the additional paragraph proposed by Mr. Timonoff. It runs as follows :

" It is desirable that in all countries where inland navigation plays or can play an important part, the study of the reciprocal influence of waterway and railway carriage should be carried out in a continuous and systematic manner, in accordance with a programme drawn up by the Permanent Commission of the Railway Congress, acting conjointly with the Permanent Commission of the Navigation Congress."

Mr. Franke. (In German.) — I propose to word this paragraph as follows :

" It is desirable that in all countries where inland navigation has played or can play an important part, the study of the reciprocal influence of waterway and railway carriage should be made in a continuous and systematic manner. From this point of view, it is advisable that a programme should be drawn up by the Permanent Commission of the Railway Congress, acting conjointly with the Permanent Commission of the Navigation Congress."

Mr. Timonoff. (In French.) — I agree to this alteration in the wording.

— The last paragraph, thus amended, is adopted.

DISCUSSION AT THE GENERAL MEETING

Meeting held on 14 July, 1910 (afternoon).

MR. P. WEISSENBACH, PRESIDENT, IN THE CHAIR.

GENERAL SECRETARY : MR. L. WEISSENBRUCH.

FIRST ASSISTANT GENERAL SECRETARY : MR. MÜRSET.

SECOND ASSISTANT GENERAL SECRETARY : DR. A. BONZON.

Mr. Bloch, *principal secretary of the 4th section*, read the

Report of the 4th section.

(See *Journal de la huitième session*, No. 5, p. 5.)

" Mr. MARLIO, in his own name and in that of Mr. Colson, set forth the principal points of their joint report. He described the relative situations of the railways and the waterways in the different countries, and emphasized the advantage the latter had of freedom from toll. He examined in succession : the cost of carriage on boats, the influence of the terminal charges, that of the system of rating of the railways on the division of the traffic between the two classes of ways, and he mentioned the other causes which could affect this division : time required for the conveyance, nature and value of the goods, class and habits of the customers, influence of large centres. He demonstrated more especially the error of the opinion, too readily accepted, that water-carriage was limited to heavy goods. He showed how river navigation facilitated the importation of foreign produce and how shipping, not readily increased and with very variable rates, generally left to the railways the burden of any excess traffic during times of over-production.

" The direct competition of railways would be easy with defective or even medium-quality waterways if it did not too frequently meet with the opposition or at least the excessive requirements of the public authorities, who in certain countries however authorized special agreements, between railways and the users of waterways. Such competition could often be made indirectly against good waterways by limiting through suitable tariffs the zone of reconsignments at the transhipports.

" Cases of cooperation of railways and waterways were very rare.

" This interesting report was supplemented by an examination of the net cost of carriage of goods in large quantities on railways; it showed that this was 1 to 1·2 centime per ton-kilometre (0·157*d.* to 0·188*d.* per English ton-mile).

" Mr. JEBB (*reporter*) set forth that in England only the Birmingham canal carried an important traffic; it served as feeder to the railways. The demands for the construction of new waterways would meet with but little response owing to the certainty of a deficient return on the capital expended and the probable refusal of any financial assistance from the State or the local authorities.

" Mr. COLSON gave a summary of Mr. W. E. Hoyt's report, as he was absent. According to this report, the very low rates of American railways took away all importance from inland navigation, which had lost its former importance both on the Erie canal and the Mississippi river. The State of New York had however undertaken to enlarge the Erie canal at a cost of over 100 million dollars (£20 millions).

" During the ensuing discussion Mr. MERCZYNG (*Russian State Railway*) drew attention to the regularizing of navigation by means of mechanical traction; Mr. TIMONOFF (*Russian government*) desired that an investigation should be made, jointly with the International Congress of Inland Navigation, on the comparative merits of railways and waterways; Mr. RICHÉ (*French Eastern Railway*) thought that such an understanding would be impossible; Mr. COLSON thought that such an investigation, by two opposing parties, would be useful in order to give partisans of navigation an opportunity for stating precisely the reasons for the superiority which they claimed; Mr. HALE (*American Railway Association*) urged that the stress of times of too much traffic fell exclusively on railways; Messrs. W. E. HOYT (*reporter*) and HAINES (*government of the United States of America*) thought that the competition of waterways with railways was impossible owing to the low rates of the latter.

" Finally Mr. COLSON read his proposed conclusions, which were slightly modified to meet remarks by Messrs. Fairfax HARRISON (*Southern Railway, United States of America*) and FRANKE (*Prussian State Railway*), and then were adopted by the 4th section in the following form."

The President. (In French.) — The following are the

CONCLUSIONS.

" The Congress notes that waterways as " a rule play a much more important part " as competitors than as feeders of rail- " ways; in the United States however, " experience proves that canal competi- " tion can not be serious. The factors " which influence the division of the " traffic between the two ways are as " follows :

" 1° *Rates*, which are generally lower " by water than by rail; this is more " especially due to the fact that railway " rates are fixed so as to remunerate the " capital spent on construction as much " as possible; on the other hand, as " regards waterways, States sometimes " supply capital and attend to the main- " tenance without remuneration, or else " are satisfied with collecting tolls which

" only exceptionally cover the cost of " maintenance; only in England is the " contrary the case, and there inland " water carriage over long distances has " become very rare. In spite of the " advantage granted everywhere else to " their competitors, railways, when free " to modify their rates for the traffic which " is competed for, without granting other " classes of traffic reductions in rates " incompatible with the charges incurred, " can easily lower their rates without " losing all their profit, and make cheaper " rates than those obtainable on smaller " waterways, with many locks and nume- " rous curves. Only with difficulty do " they reduce their rates to the level of the " freights charged on large rivers with " a gentle gradient, well regulated and " provided with the necessary equipment, " as in the case of the Rhine and the " Volga; and their rates always remain " higher than the freight on the great " lakes which are similar to inland seas.

" 2° *Terminal charges*, which have a " notable influence on the choice between " the two ways, when only one of them is " in direct connection with the establish- " ments of the consignors or the con- " signees, either because these are located " on the banks of the waterways, or " because a private siding connects them " with the railway. This factor is decisive " in the case of short distances; com- " petition begins at medium distances, " and the railway gains or loses influence, " as the distance increases, according to " whether the tariff is a differential one, " or whether on the contrary it remains " practically proportional to the distance.

" 3° *The time required for the journey*, " which is much less on the railway, " except in the case of relations where the " economical and geographical situation " of the waterway makes it possible to " use powerful steam-engines; on the " other hand water-carriage is nearly " everywhere subject to interruptions " which do not affect railways.

" 4° *The nature of the goods*, which " resist more or less well the effects of " water-carriage. It is by no means " correct (as is often said) that the line " of separation is formed by the value; " water-carriage is used for goods of a " rather considerable value per ton, when " technical and commercial conditions " make a regular service possible; its " disadvantages are then counter-balanced " by the relatively high rate which rail- " ways charge for such goods; railways, " on the other hand, can carry large con- " signments of heavy goods at as cheap a " rate as the waterway, on lines of easy " profile serving the same relations. The " objections to the longer time required " for the journey, and to the effects of " damp, may be as important for low- " price goods (coal) as for more valuable " articles.

" 5° *Direction of traffic at seaports.* — " Waterways take away from railways a " larger fraction of the import traffic than " of the export traffic, especially while " regulations and public opinion prevent " railways from applying the same reduc- " ed rates to imports as to exports and " also because direct transhipment from " ship to lighter is easier for oversea " goods carried in large quantities by sea " than for home produce which generally " arrives in small quantities from various

" parts of the country, to be shipped when " a ship is available.

" 6° *Variations in the activity of the* " *traffic*, due to the season or to econom- " ical crises. The railway has much " more flexibility in meeting sudden " changes. Variations in the activity of " business produce, in the case of rail- " ways, large variations in the amount of " traffic offered; these only in very " exceptional cases cause alterations in " the rates. On the other hand, the water- " ways retain a less variable tonnage of " the traffic competed for, by raising or " lowering their rates according to the " state of the market.

" Next considering the position of " waterways as feeders of railways, one " sees that if the latter were able to " modify their rates at their own con- " venience, they would nearly always be " able to carry consignments the whole " way, giving the public as favourable " conditions as mixed carriage would, " while at the same time realizing a " higher profit to remunerate their ca- " pital.

" A railway administration has not " much interest in cooperating with " inland waterway services (unless these " are of a quasi-marine character) except " in three cases :

" 1° When railways are prohibited " from making lower rates so as to retain " the traffic for the whole distance, as is " generally the case with imports;

" 2° When their lines are able either to " receive from waterways or to bring to " them traffic which might be carried the " whole distance by a rival railway;

" 3° When in a country where the rail- " way system does not yet provide for all " important currents of traffic, as in " Russia, the State was wise enough to " connect first by means of railways the " centres not already connected by water- " ways, so that a mixed route is the only " one possible for many articles.

" If it is necessary to establish a new " line to provide for a considerable flow " of traffic, for which existing lines do " not suffice, and when the topographical " and economic situation would make an " artificial waterway possible, the same " result can be obtained by constructing " a railway, costing less for construction " and operation; particular cases being of " course excepted.

" It is desirable that in all countries " where inland navigation has played or " can play an important part, the study of " the reciprocal influence of waterway " and railway carriage should be made in " a continuous and systematic manner. " From this point of view, it is advisable " that a programme should be drawn up " by the Permanent Commission of the " Railway Congress, acting conjointly " with the Permanent Commission of the " Navigation Congress."

— These conclusions were confirmed by the general meeting.

REPORT N° 1

(British Colonies)

By Sir THOMAS R. PRICE, K. C. M. G.,
GENERAL MANAGER, CENTRAL SOUTH AFRICAN RAILWAYS.

CONTENTS.

1. — *Memorandum by reporter and introduction.*

2. — *Principles of statistics of railways in operation.*

- *a*) General.
- *b*) Accounts.
- *c*) Statistics of physical condition of property and equipment.
- *d*) Statistics of volume and character of traffic carried.
- *e*) Unit statistics as applied to volume of traffic carried, etc.
- *f*) Statistics of cost of operation.
- *g*) Statistics relating to indirect and subsidiary services.
- *h*) Miscellaneous other statistics.

3. — *Uniform classification of railway working expenses.*

4. — *Conclusions of reporter.*

5 — *Annexures.*

PART 1.

Memorandum by reporter relative to question XIV (II of section 4).

Railways have become so important a factor in human affairs as almost to warrant the general statement that the progress and prosperity of any country depends on the extent and rate of increase of that country's railway communications and on the wisdom or otherwise of their administration. Any measures which conduce to true efficiency and economy, undoubtedly lead to the extension or extended use of such means of transport.

One of the most valuable aids to efficient management is afforded by comprehensive, well-balanced statistics and accounts, especially if they are available in time to serve the purpose of a guide to current matters. Belated figures usually serve only for purposes of record or criticism; they lose much of their value to the Administration, by reason of their failure to bring promptly to notice the warnings or suggestions which the figures convey.

Since all progress is relative, it is desirable that such statistics and accounts should afford comparisons with other periods or other systems or both, and as it is the case that the main problems connected with commercial railway working (though differing in matters of detail) are more or less the same in nearly all countries, it is clear that the adoption by all railways of uniform methods of recording their statistics and results of working would prove of inestimable value in railway management and administration.

One of the most lasting impressions derived by the writer while on a tour of the various British Colonies, Japan, the United States, Great Britain, and the continent of Europe — an impression which was strengthened by a visit on a later occasion to Egypt and British East Africa — was this international similarity of problems relating to railways and harbours, and the regrettable absence of any system which would render the experience of one country sufficiently and readily available to the other. The possession of such information would over and over again have meant the saving of large sums of money, and would have ensured constantly increasing efficiency and progress. This conviction has only been deepened by subsequent experience and observation.

It is perhaps too much to hope for absolute uniformity in railway statistics in the immediate future since there is such great diversity in the statistical needs of the various railways in different parts of the world, but the discussion by the Conference of the principles of such statistics cannot fail to have a very powerful influence in the direction of securing greater uniformity and utility in the future than has been possible in the past.

So far as the classification of railway working expenditure is concerned, however,

the arguments in favour of uniformity are so convincing, and the advantages of being able to institute comparisons between one system and another are so pronounced as to compensate amply for any inconvenience and expense which would be entailed by changes in existing expenditure classifications. It is to be hoped that the deliberations of this Conference will result in the adoption of a recognised standard form of accounts and classification of expenditure for all railways at an early date.

The writer of this paper feels that he can best serve the purpose the Congress has in view by emphasising the importance of securing such uniformity. If, for the purpose of bringing into relief existing differences he has trespassed on the railway area entrusted to other reporters in order to contrast the practice of other countries with that of British Colonies, his doing so will, it is hoped, not be misunderstood.

INTRODUCTION.

Method adopted in preparation of papers.

In order to obtain information for a survey of the conditions obtaining at the present time in the British Colonies and Possessions, it was necessary to submit to the different Administrations a long series of questions dealing with the two branches of the subject of "Statistics". Information was sought in all from forty-one railways, and I have to express my very sincere thanks to the officers engaged in their administration for the large amount of time and trouble taken by them in furnishing the exhaustive information contained in their replies. Particulars of the railways from which information was sought and the extent to which such Administrations have been able to accede to my request for particulars of their practice, are given in the following table.

As might be expected, the railway systems in the British Colonies have in the main followed British practice in regard to the preparation of statistical data, and also in the classification of their working expenditure.

In most cases, such railways are the property of the Government, or the Government has entrusted their operation to a company for a term of years, but retains such a large amount of control in the meantime as to leave the influence of State ownership practically untouched. The capital required for the construction of the lines was in almost every case raised in Great Britain, and the staff was, at the outset, mainly drawn from English railways.

The Governments of the Colonies concerned in the construction of railway lines would, in the first instance, naturally adopt the expenditure heads laid down by Parliament for English railways, rather than frame special heads of their own. With this classification, the staff would be familiar by reason of their English training, and their adherence to it would be a matter of habit. Occasionally, special or local circumstances would imperatively demand some departure from the recognised model, in the shape perhaps of a new sub-head or item of expenditure which did not fit in with the English classification, or publice opinion (somtimes expressed

in Parliament, sometimes outside of it) would demand a more detailed classification to admit of more efficient control being exercised.

Of late years, other potent factors have been at work in bringing about modifications of the original type of classification in the colonies.

In the preparation of the attached papers, the writer has naturally been influenced to a considerable extent by South African practice and particularly by methods followed on, and experience derived from the administration of, the Central South African Railways.

In the case of these latter railways, economical working is of especial importance, for the two Colonies they serve (*viz.*, the Transvaal and the Orange Free State) are a long way from the coast, and there is an entire absence of navigable waterways or other means of reliable and cheap transport apart from railways. Consequently, the aids rendered by statistics and other means have been largely availed of. Advantage has also been taken to the utmost possible extent of the experience of other countries in deciding upon the accounts and statistics calculated to best meet the requirements.

The system of accounts at present adopted by the Central South African Railways is partly based on that of the Buenos Ayres Great Southern Railway of South America (which was itself adopted, it is understood, on the advice of a leading firm of British Chartered Accountants) and partly on the classifications issued by the United States Inter-State Commerce Commission, with the addition of French, British, and colonial elements where such seemed well adapted to local conditions.

In analysing the replies received and the information contained in the printed reports received from the different Colonial Railway Administrations, an attempt has been made to adhere, as far as possible, to the subdivisions given in the list of subjects furnished by the Congress, *viz.* :

A. — Principles of Statistics of Railways in operation;
B. — Uniform Classification of Working Expenses.

But it is obviously difficult to draw a hard and fast line between two branches of a subject so closely related, and in order to facilitate separate treatment, a certain amount of repetition has been unavoidable.

List of the British Colonial Administrations to which papers of questions were sent showing those from which replies were received.

PART 2.

Principles of Statistics of Railways in operation.

a) General.

To the older railway official, few things are more noticeable than the change which has taken place in recent years in the attitude of those engaged in the business of transportation in regard to railway statistics, and the increasing recognition there now is of the value of such statistics as a means of securing the best results in working. Formerly, statistics were regarded as particularly useful in bringing about reductions of staff and in indicating possible economies in other directions, the effecting of such economies being regarded as an end in itself rather than as a means to an end.

At the present time, the value which such statistics of operation possess in securing economical working is still omitted, but more adequate recognition is accorded to the possibilities which any reductions in cost (or increases in efficiency) open up in the way of increased traffic and increased employment of staff. More importance is therefore now attached to statistics of traffic carried, and other figures likely to indicate directions in which expansion is possible.

In this connection, it is necessary to remember that of the total revenue earned by an average railway approximately 40 per cent is required to meet charges such as interest (or dividends) on capital. Of the remaining 60 per cent, authorities differ as to the average proportion consisting of expenditure which can be readily adjusted to any variation in the traffic offering, as distinct from what may be regarded as fixed operating charges (such as the cost of absolutely necessary material for maintenance or up-keep and the pay of such of the Executive and Administrative Staff, Station, Locomotive, Permanent Way, Stores, and Accounting Staff, as must be employed and paid irrespective of the conditions of trade), but one-half may be taken as a fair approximate average. That is to say, the scope for effecting economies in working expenditure does not, on the average railway, usually exceed 30 per cent of the gross receipts — the rest of the expenditure is more or less beyond the control of those entrusted with actual operation.

This aspect of the question serves to emphasise the advantage of seeking to secure improvements in financial working results by encouraging the development of such traffic as statistics show to be of a profitable nature.

Object of preparation of railway statistics.

The object of preparing statistics of railway operation should, in the opinion of the writer, be regarded as fourfold :

1° To present a clear idea of the general physical condition of the property;

2° To give full information as to the transportation services rendered and the remuneration received for such services, with a view to indicating directions in which it is possible to foster traffic;
3° To indicate the cost of doing the work and the directions in which it is possible to reduce such cost without detriment to efficiency;
4° To indicate the social and economic aspects of operation as affecting the public in general and the staff employed in particular.

Accounts and statistics : relation between.

While it is true that the figures recorded in the accounts of a railway form an important section of the statistics necessary for efficient administration and are the basis of some of the other statistics as well, it is the opinion of the writer that a clearer distinction than is usually made should be observed between the respective spheres of accounts and statistics, and in this paper an attempt has been made to separate matters of accounts from those statistics which are usually prepared for the special assistance and guidance of operating officers.

The latter class of statistics may be aptly divided into two sections, *viz.* :

1° Temporary;
2° Permanent.

Temporary statistics.
